(Vol 255)
No 5503-9
and 311
May-June
1975

When it comes to mRNA, we're great isolationists.

By affinity chromatography on Oligo dT-Cellulose, you can easily and efficiently isolate the many active messenger RNA's that have poly rA rich regions.

And that's where the isolationists of Collaborative Research get involved. Our ability to synthesize and produce high quality insolubilized oligonucleotides for affinity chromatography has made us leaders in the field.

We make available several different types of oligo dT-Celluloses. The first (Catalogue #T-1) is used in the purification of enzymes such as RNA-dependent DNA polymerase. The second type (#T-2) is specifically for isolating and purifying mRNA's containing poly rA sequences. The third (#T-3), also for purifying mRNA, contains longer nucleotide chain lengths for greater binding capacity. These three oligo dT-Celluloses from Collaborative Research are the standards world wide.

Our Oligo dT-Celluloses are assayed for their ability to bind both poly rA and mRNA. In salt solutions such as 0.5M, you can obtain poly rA binding as high as 150 A_{260} units per gram. mRNA binding is quantitative.

If your research could benefit by our insolubilized oligonucleotides for affinity chromatography, or from any of our other work with nucleic acids, let us send you further information. Just send us this coupon.

RP381

- ☐ **Oligo dT-Cellulose for isolation of mRNA**
- ☐ **Ribo & Deoxyribo-Oligonucleotides of defined sequence**
- ☐ **Template-primers & Assay kits for Reverse Transcriptase**
- ☐ **DNA-RNA & DNA-DNA hybrids**
- ☐ **Custom synthesis**
- ☐ **RIA's for Cyclic AMP & Cyclic GMP**

[illegible]

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Evidence for nuclear control of amino acid transport in cultured cells—*S. P. Hume, J. F. Lamb and R. Weingart* 7
Specificity of cellular retinol-binding protein for compounds with vitamin A activity—*D. E. Ong and F. Chytil* 7
Identification of the biochemical lesion produced by α-chlorohydrin in spermatozoa—*H. Mohri, D. A. I. Suter, P. D. C. Brown-Woodman, I. G. White and D. D. Ridley* 7
Localisation of plutonium in mouse testes—*D. Green, G. R. Howells, E. R. Humphreys and J. Vennart* 7
Modification of drug biotransformation by vitamin C in man—*J. B. Houston and G. Levy* 7
Tryptophan pyrrolase activity regulation in *Drosophila:* role of an isoacceptor tRNA unsettled—*D. Mischke, P. Kloetzel and M. Schwochau* 7
Effects of cordycepin and cordycepintriphosphate on polyadenylic and ribonucleic acid-synthesising enzymes from eukaryotes—*G. Maale, G. Stein, and R. Mans* 8
Different ultraviolet DNA endonuclease activity in human cells—*N. J. Duker and G. W. Teebor* 8
Rolling circular DNA associated with Dane particles in hepatitis B virus—*L. R. Overby, P. P. Hung, J. C.-H. Mao, C. M. Ling, and T. Kakefuda* 8
Chemical and immunological differences between normal and tumoral colonic mucoprotein antigen—*D. Gold and F. Miller* 8
Difference between the two iron-binding sites of transferrin—*J. V. Princiotto and E. J. Zapolski* 8

[illegible] Library
SCIENCE COLLEGE

Oxford Books for Students

Oxford Physics Series

Four forthcoming volumes

Space Physics

The Study of Plasmas in Space

R. L. F. Boyd

In the study of geophysical and astrophysical phenomena the advance by space research has been so rapid – and the manned adventure has so dominated attention – that it is difficult for the undergraduate student to gauge the impact of the new techniques. *Space Physics,* which covers ionospheres, magnetospheres, the atmosphere of the sun, and cosmic X-ray astronomy, is written largely from the author's own experience in space science since 1954. £3.50

The Solid State

An introduction to the Physics of Crystals for Students of Physics, Materials Science, and Engineering

H. M. Rosenberg

This is a textbook for students new to solid-state physics or materials science. The topics covered include basic crystal structure, diffraction, defects, dislocations, specific heat, phonons, thermal and electrical conductivities of metals, insulators, and semiconductors, the physics of the p-n junction, and magnetic and dielectric properties. £6.50 paper covers £2.25

Special Relativity

John G. Taylor

Using the fact that the speed of light is constant, the author of this book shows how space and time are distorted by high-speed motion, and he describes the quantitative measure of these effects and their combination in the Lorentz transformation. He considers dynamical effects for colliding particles and then for charged particles and their associated electric fields, which leads to analysis of the Lorentz transformation, the Lorentz group, and an introduction to its representations. £4 paper covers £1.95

Surface Physics

M. Prutton

This book, based on a short course for final-year undergraduates in physics, describes the reasons for studying surface physics, the problems for which answers are required, the techniques that are available, and some of the answers they have produced. £2.75

Inspection copies of these books are available to lecturers wishing to consider them for adoption as required texts. Please write, giving details of the course and the number of students involved, to Oxford University Press (UPS), Ely House, 37 Dover Street, London W1X 4AH.

Introduction to Control Theory

O. L. R. Jacobs

This book gives a uniform presentation of the main results of classical control theory, optimal control theory, non-linear methods, and stochastic control theory. The mathematical level is that of final-year undergraduate courses in engineering science, but the book is accessible to anybody with some knowledge of ordinary linear differential equations, the elements of probability theory, complex numbers, and matrix algebra. £6.75

Principles and Problems in Physical Chemistry for Biochemists

Nicholas C. Price and Raymond A. Dwek

Student biologists and biochemists are here introduced to physical chemistry by means of worked examples and problems (with detailed answers) and brief, concise explanations of the most important theoretical points. The text is developed logically and shows the student how it is possible, by using thermodynamic quantities, to predict whether a process can occur, and from kinetic studies to predict how fast this will happen. £5.50 paper covers £2.35

Mathematical Analysis and Techniques

A. Page

This treatment of analysis is based on the needs of students taking mathematics as part of a degree or HND in science or engineering. It also provides a textbook for those interested in the practice of mathematics and a useful introduction to the more abstract texts. The subjects covered include, in Volume I, functions of two or more variables and double integrals and, in Volume II, differential equations, matrices, and functions of a complex variable. £2.50 each *Oxford Mathematical Handbooks*

A First Course in Combinatorial Mathematics

I. Anderson

This is an introduction to the basic combinatorial tools such as recurrence relations, generating functions, incidence matrices, and the inclusion-exclusion principle. A study of block designs is followed by a brief mention of applications to coding theory, and in the final chapter Steiner systems and sphere-packing problems are related via the famous Leech lattice. The book is intended for undergraduates at universities and polytechnics, for whom it provides a standard course for such students with plenty of examples to work on. £3.75 paper covers £1.35 *Oxford Applied Mathematics and Computing Science Series*

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. Radioimmunoassay?

Searle Diagnostic now supply from stock and by return of post the following antisera for radioimmunoassay, freeze-dried in vials, containing sufficient for 200 tubes

- **Anti-testosterone-3-BSA** (sheep)
- **Anti-17β oestradiol-6-BSA** (sheep)
- **Anti-testosterone-3-BSA** (rabbit)

These products, the first of a range, have been developed from routine use and research into steroids in the Searle Scientific Services Laboratory

Steroid Antisera for Radioimmunoassay

Refined Carbohydrate Foods and Disease

Some Implications of Dietary Fibre

edited by D. P. Burkitt and H. C. Trowell

June/July 1975, xiv+352 pp., £7.80/$20.75 0.12.144750.2

This important and extensively documented book provides considerable evidence that many western diseases may be related to a reduction in consumption of dietary fibre, which includes celluloses, hemicelluloses and lignin. Hitherto these substances have been almost totally neglected in food technology. With the modern tendency to process foods for convenience, cereal foods in particular suffer from the removal of this fibre which is essential for the fulfilment of certain physiological functions: research shows its deficiency can be one of the causes of such critical diseases as ischaemic heart disease, tumours of the large bowel, diverticular disease, gallstones, appendicitis, varicose veins, haemorrhoids, obesity and diabetes.

No other book contains so much conclusive scientific evidence incriminating fibre-depleted starchy food as a major pathological agent. The contributors regard the evidence supporting this thesis as being of far greater significance than that which emphasises the dangers of high levels of sucrose consumption.

Hybridization and the Flora of the British Isles

edited by C. A. Stace

June/July 1975, £14.80/$39.25 0.12.661650.7

Every one of the 975 hybrids that has been recorded from the British Isles is represented in this volume. Up-to-date data are provided on their appearance, identification, fertility and distribution, and on the results of any experimental work which has been carried out on them. Many of the so-called hybrids are mere fanciful identifications; the evidence in such cases is assessed. A literature list is given for each hybrid, and an introductory section provides a general background to the whole subject of hybridization. In addition, 464 hybrids between British species which have been found abroad but not yet in the British Isles are listed.

The Biology of the Male Gamete

Supplement No. 1 to the Biological Journal of the Linnean Society, Volume 7, 1975

edited by J. G. Duckett and P. A. Racey

June/July 1975, xviii+590 pp., £15.00/$39.75 0.12.223050.7

This symposium aims to bring together diverse aspects of the biology of the male gamete of animals and plants, to relate their structure to their function and to establish the extent of common ground between them. The book, which is extensively illustrated with many previously unpublished micrographs, contains up-to-date reviews coupled with the results of recent research by recognized specialists. The treatment of the plant kingdom is especially comprehensive with papers on the male gametes of algae, fungi, archegoniates and angiosperms. Contributions on animal gametes deal not only with topics of perennial interest such as motility and survival, but also with recent research on sperm proteins and enzymes.

Chemical Oceanography

2nd Edition (Expanded from 2 to 6 volumes)

edited by J. P. Riley and G. Skirrow

This second edition of a much used and highly praised work will be invaluable to research workers in oceanography, to those newly entering the field, and to those in peripheral study areas, such as marine biologists and geologists.

Volume 2

June/July 1975, xx+648 pp., £19.50/$51.75 0.12.588602.0

Contents

Geoffrey Skirrow: The dissolved gases—carbon dioxide. **Peter S. Liss:** Chemistry of the sea surface microlayer. **C. P. Spencer:** The micronutrient elements. **P. J. le B. Williams:** Biological and chemical aspects of dissolved organic material in sea water. **T. R. Parsons:** Particulate organic carbon in the sea. **G. E. Fogg:** Primary productivity. **K. Grasshoff:** Land-locked seas and estuaries. Subject index.

Crystal Growth from High-temperature Solutions

D. Elwell and H. J. Scheel

June/July 1975, xiv+630 pp., £19.80/$52.25 0.12.237750.8

This work will be welcomed as the first to cover in detail all aspects of this technique for crystal growth. The authors close the gap between the theory of crystal growth from solutions and the practice of 'flux growth', and give a comprehensive description of the experimental aspects such as crucibles, thermo-couples and temperature control. An important feature is the list of crystals grown from high-temperature solutions, together with experimental data and about 2,500 references. The important and often neglected subject of crystal characterization is treated in depth.

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (*a*) is preferred to e^a if '*a*' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Non-random occurrence of 7-14 translocations in human lymphocyte cultures—*J. P. Welch and C. L. Y. Lee, J. W. Beatty-DeSana, M. J. Hoggard and J. W. Cooledge; F. Hecht, B. K. McCaw, D. Peakman and A. Robinson* 241

Factor suppressing α-foetoprotein production in newborn mice—*B. G. Tumyan, G. G. Svet-Moldavsky and N. V Karmanova* 244

NOW THERE'S ONE SCIENCE FOR ALL SOCIAL CREATURES.

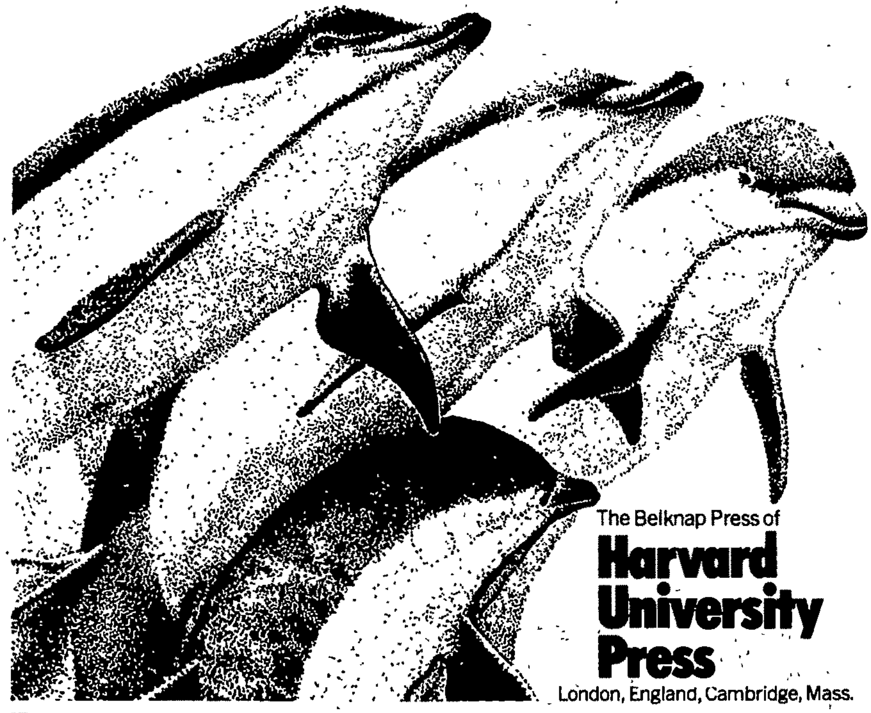
Sociobiology

The New Synthesis
by Edward O. Wilson

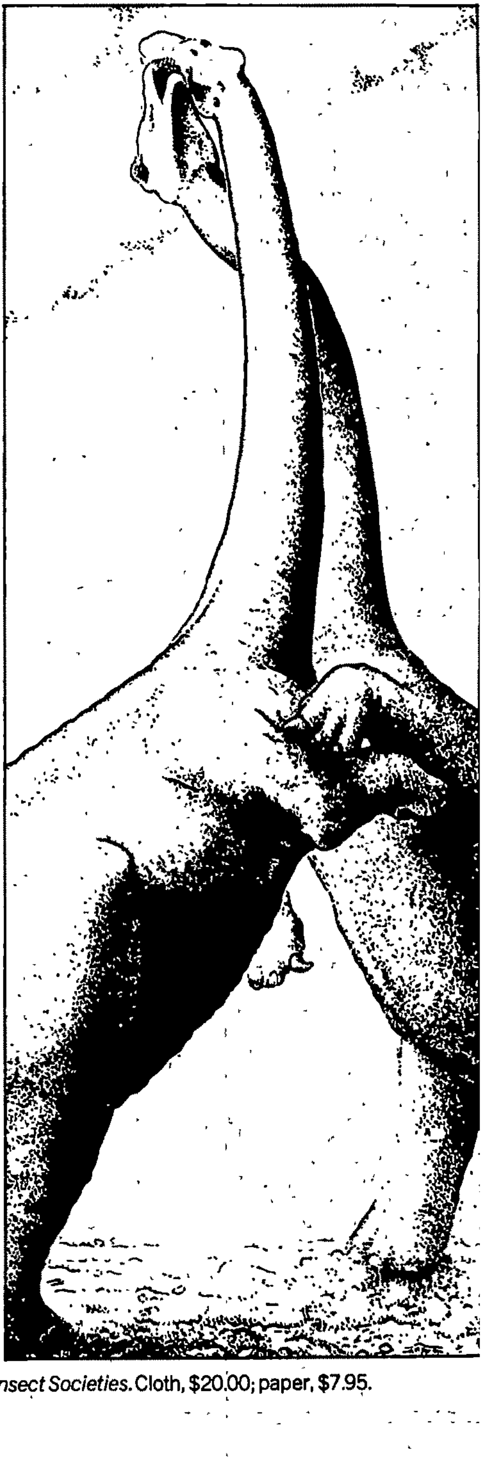
For the first time the whole range of social creatures—from bacteria to termites, from monkeys to mankind—is described in depth and within the framework of modern biology.

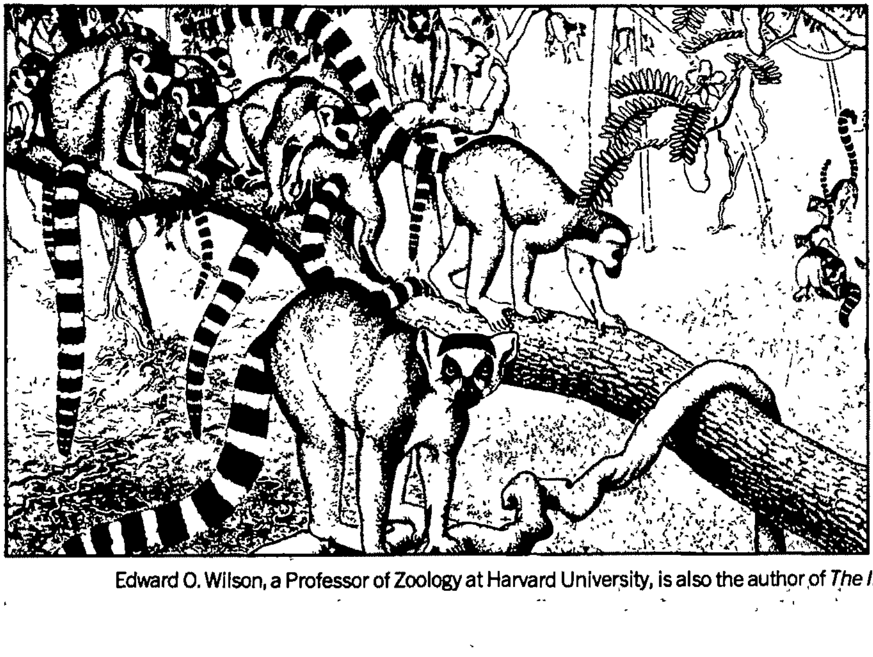
Sociobiology is the systematic study of the biological basis of all social behavior. It provides a wealth of information about animal societies. And is indispensable to anyone seeking to understand the human situation.

Sociobiology is fully, and magnificently, illustrated by Sarah Landry. $20.00



The Belknap Press of
Harvard University Press
London, England, Cambridge, Mass.





Edward O. Wilson, a Professor of Zoology at Harvard University, is also the author of *The Insect Societies*. Cloth, $20.00; paper, $7.95.

Pure Chemistry Library
SCIENCE COLLEGE

Oxford Books for Students

Oxford Physics Series

Four forthcoming volumes

Space Physics

The Study of Plasmas in Space

R. L. F. Boyd

In the study of geophysical and astrophysical phenomena the advance by space research has been so rapid – and the manned adventure has so dominated attention – that it is difficult for the undergraduate student to gauge the impact of the new techniques. *Space Physics,* which covers ionospheres, magnetospheres, the atmosphere of the sun, and cosmic X-ray astronomy, is written largely from the author's own experience in space science since 1954. £3.50

The Solid State

An Introduction to the Physics of Crystals for Students of Physics, Materials Science, and Engineering

H. M. Rosenberg

This is a textbook for students new to solid-state physics or materials science. The topics covered include basic crystal structure, diffraction, defects, dislocations, specific heat, phonons, thermal and electrical conductivities of metals, insulators, and semiconductors, the physics of the p-n junction, and magnetic and dielectric properties. £6.50 paper covers £2.25

Special Relativity

John G. Taylor

Using the fact that the speed of light is constant, the author of this book shows how space and time are distorted by high-speed motion, and he describes the quantitative measure of these effects and their combination in the Lorentz transformation. He considers dynamical effects for colliding particles and then for charged particles and their associated electric fields, which leads to analysis of the Lorentz transformation, the Lorentz group, and an introduction to its representations. £4 paper covers £1.95

Surface Physics

M. Prutton

This book, based on a short course for final-year undergraduates in physics, describes the reasons for studying surface physics, the problems for which answers are required, the techniques that are available, and some of the answers they have produced. £2.75

Inspection copies of these books are available to lecturers wishing to consider them for adoption as required texts. Please write, giving details of the course and the number of students involved, to Oxford University Press (UPS), Ely House, 37 Dover Street, London W1X 4AH.

Introduction to Control Theory

O. L. R. Jacobs

This book gives a uniform presentation of the main results of classical control theory, optimal control theory, non-linear methods, and stochastic control theory. The mathematical level is that of final-year undergraduate courses in engineering science, but the book is accessible to anybody with some knowledge of ordinary linear differential equations, the elements of probability theory, complex numbers, and matrix algebra. £6.75

Principles and Problems in Physical Chemistry for Biochemists

Nicholas C. Price and Raymond A. Dwek

Student biologists and biochemists are here introduced to physical chemistry by means of worked examples and problems (with detailed answers) and brief, concise explanations of the most important theoretical points. The text is developed logically and shows the student how it is possible, by using thermodynamic quantities, to predict whether a process can occur, and from kinetic studies to predict how fast this will happen. £5.50 paper covers £2.35

Mathematical Analysis and Techniques

A. Page

This treatment of analysis is based on the needs of students taking mathematics as part of a degree or HND in science or engineering. It also provides a textbook for those interested in the practice of mathematics and a useful introduction to the more abstract texts. The subjects covered include, in Volume I, functions of two or more variables and double integrals and, in Volume II, differential equations, matrices, and functions of a complex variable. £2.50 each *Oxford Mathematical Handbooks*

A First Course in Combinatorial Mathematics

I. Anderson

This is an introduction to the basic combinatorial tools such as recurrence relations, generating functions, incidence matrices, and the inclusion-exclusion principle. A study of block designs is followed by a brief mention of applications to coding theory, and in the final chapter Steiner systems and sphere-packing problems are related via the famous Leech lattice. The book is intended for undergraduates at universities and polytechnics, for whom it provides a standard course for such students with plenty of examples to work on. £3.75 paper covers £1.35 *Oxford Applied Mathematics and Computing Science Series*

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Cyclic AMP and Adenyl Cyclase

-we've got the measure of both

The only commercially available cyclic AMP kit for

- Direct assay of plasma cyclic AMP without tedious extraction methods or recovery corrections
- Simple and accurate assay of adenyl cyclase activity free from non-specific interference
- Confidence in results by eliminating errors in crude tissue extracts
- Convenient double linear plotting of results and freeze dried reagents for maximum stability and storage time

Our cyclic AMP assay kit makes use of the high specificity and affinity for cyclic AMP of a highly purified and stabilized binding protein from bovine muscle. This is combined with an improved charcoal separation step. The result is freedom from interference in the assay of adenyl cyclase by materials likely to be present in crude tissue extracts. Also by measuring cyclic AMP formed from cold ATP most of the difficulties encountered in adenyl cyclase assays using labelled ATP are eliminated. Full information available on request.

Collected Nature

These specially designed Binders make attractive space-saving files for your **Nature**. Bound in durable black imitation leather, lined with grey deer skin and beautifully labelled, each binder will hold up to eighteen copies of **Nature**. Two volumes of **Nature** can be preserved in a single binder, (three binders will hold the six volumes published annually) and there is a white space on the spine to enable you to mark each binder with your own reference to the issues it contains.

These binders are offered for sale singly for £1.85 or in packs of three for £5.00. Both prices include postage by surface mail and V.A.T. To order please complete the coupon below and return it with the appropriate remittance.

NATURE, Macmillan Journals Limited, Brunel Road, Basingstoke, Hampshire RG21 2XS.
Please send me:
1 NATURE BINDER (I enclose £1.85)
3 NATURE BINDERS (I enclose £5.00)
(Payment may be made in any currency at the current rate of exchange) Prices applicable only to orders received before the 30th June 1975. Orders can only be serviced if accompanied by remittance, cheques should be made payable to Macmillan Journals Limited.

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width.' The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Kinetics of Enzyme Mechanisms

J. Tze-Fei Wong

June/July 1975, xi+294 pp., approx. £8.00 0.12.762250.0

Most of the chemical reactions that take place in living organisms are catalysed by specific enzymes. Much information concerning the mechanism of an enzyme-catalysed reaction may be obtained by kinetic studies, where the rate behaviour of the enzyme is observed under varying conditions. This book contains previously unpublished material examining the wide-ranging concepts and methods developed to interpret the behaviour of different classes of enzyme mechanisms. It conveys the essential ideas behind various mathematical kinetic methods with a minimum of mathematical detail.

A NATO Advanced Study Institute

Algebras in Analysis

Proceedings of an instructional conference organized by The London Mathematical Society

edited by J. H. Williamson

June/July 1975, xii+312 pp., £10.80/$28.50 0.12.757150.7

This volume makes available to the mathematical public a record of the proceedings of the "Algebras in Analysis" conference held in Birmingham in September 1973. All the invited course of lectures are included, as well as some other contributions from participants. The aim of the meeting was to provide an opportunity for graduate students approaching doctoral standard, and also established mathematicians, to learn of important recent developments in functional and harmonic analysis. The courses, by acknowledged experts, range widely and do not all pre-suppose the same level of mathematical background or sophistication in the reader: however, all should be valuable introductions to recent and current research work in the area.

Intestinal Absorption in Man

edited by Ian McColl and G. E. G. Sladen

June/July 1975, x+364 pp., approx. £11.00 0.12.482150.2

This book is a collection of essays on various aspects of intestinal absorption in man. Although the emphasis is on human studies, reference to animal work is included particularly where data on human intestinal absorption is scanty or unavailable. The book is not intended to be a comprehensive review and the absorption of folate andvitamin B12 has been omitted altogether.

Contents

G. E. Sladen: Methods of studying intestinal absorption in man. G. E. Sladen: Absorption of fluid and electrolyte in health and disease. H. B. McMichael: Absorption of carbohydrates. M. D. Hellier and C. D. Holdsworth: Digestion and absorption of proteins. M. L. Clark and J. T. Harries: Absorption of lipids. C. D. Holdsworth: Calcium absorption in man. B. Brozovic: Absorption of iron. I. M. Coupar and Ian McColl: The pharmacology of absorption. Index.

Man-Made Lakes and Human Health

edited by N. F. Stanley and M. P. Alpers

June/July 1975, xvi+496 pp. £12.40/$32.75 12.663550.1

The contributors, concerned by the effect of man-made lakes on human health and the general ignorance of this relationship, present the ways in which dams produce gross and sudden interference with established ecosystems. The articles are divided into four main sections—health problems, specific geographic areas, ecological factors and the human aspect. Emphasis is placed throughout on the mistakes of the past, the dangers of the future and the importance of international planning and co-operation. By defining the basic problems involved, illustrating the need for further action, indicating possible solutions, providing lines for further research, and outlining the nature of future effective action, the contributors hope to provide sufficient accurate data to enable Governments, Public Health Authorities and the scientific community to make intelligent decisions about man-made lakes.

Negative Strand Viruses

edited by R. D. Barry and B. W. J. Mahy

Volume 1

May/June 1975, xviii+550 pp., £14.50/$38.25 0.12.465301.4

Volume 2

June/July 1975, xiv+414 pp., £10.50/$27.75 0.12.465302.2

This is the first publication dealing with properties common to the 'negative strand' viruses, so called because they possess single-stranded genetic material which is of the opposite sense to that required for protein synthesis. The viruses involved are large lipid-containing RNA viruses, including the influenza, para-influenza, and rhabdoviruses. The biological properties of virus membranes and the interaction of viruses with cell membranes are considered, in detail, and one of the special features of this collection of articles is a novel theory concerning the origins of pandemics of influenza.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Chemistry of the Atmosphere

MURRAY J. McEWAN and
LEON F. PHILLIPS

This book is intended to serve as an introduction to atmospheric chemistry for those with a background in chemistry or chemical physics, and can be used as the basis of advanced undergraduate or graduate courses. In addition the text provides up-to-date reviews of recent work on the composition and dynamics of the chemosphere, the airglow, the ionosphere, air pollution, and the atmospheres of other planets.

Probable Publication July £9.75 net

An Introduction to

The Chemistry of Rocks and Minerals

MAX B. PERRIN

This book deals with the application of chemistry to geology, mineralogy and mineral technology at a level suitable for sixth form and technical college students and for undergraduates taking introductory courses in geology and geochemistry. The text provides an outline of the application of chemical concepts to geological problems, particularly those relating to the location and exploitation of mineral reserves.

Probable Publication July Cloth £3.80 net
Paper £1.90 net

Simple Nervous Systems

Editors: P. N. R. USHERWOOD and
D. R. NEWTH

The book consists of papers delivered at an international symposium held in Glasgow and Edinburgh in 1973. The subject matter is from a wide range of research projects in neurophysiology which have relevance in both biological and medical fields.

Publishing June £12.50 net

Ultrastructure and the Biology of Plant Cells

BRIAN E. S. GUNNING and
MARTIN W. STEER

More than 220 largely original and previously unpublished electron micrographs (mostly taken using transmission electron microscope, but including light and scanning micrographs as aids to 'orientation') are the basis of this essentially visual approach to the structure and function of the internal components of plant cells. Each of the plates carries a comprehensive caption which is integrated with the text by a simple cross-referencing system. The bibliography contains 1000 entries. This book can be used in conjunction with *Plant Cell Biology—an ultrastructural approach*, by the same authors (see below)

Publication July £27.50 net

Plant Cell Biology
—an ultrastructural approach

BRIAN E. S. GUNNING and
MARTIN W. STEER

Teachers and students of biology in both schools and universities have for a long time needed a reasonably-priced and up-to-date collection of illustrations depicting the ultrastructure of plant cells. The 49 plates presented here cover major aspects of cell biology particularly in relation to plant cells. The pictures, together with their comprehensive captions give a wide-ranging view of the subject and can be used in a variety of teaching and learning situations. Teachers will find the larger volume, *Ultrastructure and the Biology of Plant Cells* by the same authors, (see above), a great asset in preparing courses for which members of the class could use this set of illustrations.

Science policy must keep pace with science

For the past few years the Organisation for Economic Cooperation and Development (OECD) has been brooding on the so-called research system—the network of organisations which support and do scientific research, be it fundamental or applied, military or ecological. Eight European countries, Canada and the United States have been subjected to an examination of how they run their science, and the last report rounding off the series with conclusions and a string of recommendations is recently out. At least, the book version is newly published—it has been circulating in *samizdat* in varying degrees of confidentiality for the best part of a year (*The Research System,* **3**; OECD Paris, £3.80).

The problem with reports from international organisations is that they are bound to be toothless, and therefore less than compulsory reading. Nothing fixes the mind more when reading a White Paper than the knowledge that the author is committed to converting proposals into reality within a few months. An OECD document can be dismissed as reflecting the opinions of a staff with necessarily limited access to information and no powers to implement proposals. To do so with this document, however, would be to fail to appreciate the value of a relaxed international perspective on the remarkable phenomenon of the turning of various scientific tides around 1970 and the attempts (and sometimes failures) of scientists and administrators to cope with the new scenery of the 1970s. The report, and particularly the conclusions, dry as they may seem, could with profit be read by any scientist who worries about what he will be doing in five years time.

Part of the OECD's theme is that the pursuit of major strategic objectives, particularly in defence, nuclear energy and space, started to falter in the late 1960s and since then the main running has been taken up by matters of more common concern both nationally and internationally, such as the environment, community services and health. Few would doubt this, though for good measure graphs are included which show among other things that in the past ten years public expenditure on health research and development at least doubled in real terms whereas defence expenditure remained static. Indeed in Canada research and development on health has risen eight-fold in ten years, and is now as great as research and development expenditure on defence.

With the decline of the "major strategic objective" as a dominant force in science, however, have the mechanisms for evolving science policy changed accordingly? For the OECD sees several sacred concepts of the 1960s as being no longer accepted as axiomatic.

- The Humboldt principle that teaching and research are inseparable "may have done more harm than good" by prejudicing the evolution of research and its vitality as much as prejudicing teaching.
- The search for a 'Magic Figure' for the percentage of GNP spent on research and development has lost much of its meaning with the manifest scientific and technological successes of small-spending countries.
- The idea that fundamental science should have a certain percentage (often quoted as 10%) of total expenditure on research and development devoted to it is 'little more than folklore'.
- The concept of peer selection for the disposition of money for research to a principal investigator "does not seem to have guaranteed the quality of research so much as it has consolidated its regular advance along beaten tracks".

By this analysis the scientific community found itself caught short by the change in priorities imposed on it and tended to rationalise the swing away from the hard sciences among students as "an easy and even amateurish choice inevitable in a mass university open to all". But maybe these young people had a premonition of the future requirements of society; if sustained long enough the premonition would become self-fulfilling.

The changes that science and technology have undergone and will continue to undergo are not such as will throw thousands out of work, and they are not immediately detectable by scanning the scientific literature for a discontinuity of some sort. Nevertheless they are profound in that the earliest effects appear amongst science's latest recruits—and science has traditionally depended on the young. They are also profound in that they move science into a more political environment and a world in which there are nothing but complex answers to the simplest of questions. Can science-policymaking cope with the transition and can the sort of institutions established under past policymaking (or lack of it) fulfil a continued useful role? Two of the OECD's points deserve more debate in the British context.

First, the arena in which the support for and use of science is discussed should be broadened to permit the participation of "the young, the quiet, the not-so-eminent". Academics, foundations and learned societies should be encouraged to "equip themselves with the means for participation". Second, the countries which OECD believes have tried best to adapt to new dimenisions have been those where ministries have been constituted with wide responsibilities for "coordinating and animating scientific effort"—Science Ministries, without other sectoral responsibilities.

The need for a science ministry is not immediately apparent in Britain, especially at a time when many scientists are still readjusting to the organisational changes of the last three years. But the need for somewhere to discuss how the management of science should be conducted in 1980 is all too obvious; not in a one-day meeting but as a regular open forum where the young, quiet and not-so-eminent can learn and be heard. Council for Science and Society, please note.

Malaise of clinical organ grafting

Professor Roy Calne, of Addenbrooke's Hospital, Cambridge, considers why organ grafting in the UK is in the doldrums.

MORE than 10 years ago an immunosuppressive regimen of the thiopurine Imuran, together with corticosteroids, was introduced and clinical organ grafting became possible. The actions of these agents are not fully understood; they can be toxic and sometimes they are totally ineffective at the maximum tolerated dosage. Nevertheless more than 20,000 kidneys have been transplanted in patients treated with Imuran and steroids, and the results are far from discouraging, especially in allografts between close relatives. Rejection remains the chief barrier to progress, but the quality of the organ when grafted is also very important. In grafts between identical twins where there can be no rejection and the organ, coming from a live donor, should be in perfect condition, there is an 86% chance of the graft sustaining the patient's life at two years and the longest period of survival after operation is now more than 18 years. If a kidney is grafted from a blood relative who is not an identical twin, the figures fall to 70% and 15 years, and with a cadaver donor (in which case both rejection and the condition of the organ are likely to raise problems) the figure is 48% and 11 years.

Two inter-related factors are responsible for the present malaise, namely the lack of a significant advance in the control of rejection and the poor therapy offered to patients, compared with what could be possible using existing techniques.

Then years ago the mood of surgeons and immunologists was full of optimism. They felt that if results such as those described above could be obtained with the earliest immunosuppressive agents investigated, surely more effective and less toxic drugs would soon be available. Moreover, immunology, which had been stagnating during the previous three or four decades, was given an immense boost. The work of Medawar and his colleagues led to the successful recruitment of brains and funds into transplantation biology. As had been anticipated, this focus of interest soon bore fruit in the form of knowledge of cellular and humoral immune mechanisms. How disappointing it was to realise that this new light revealed that phenomena that had seemed simple were in reality excessively complicated and that almost every attempt to apply successful experimental techniques of graft prolongation in inbred rodents to outbred animals including man led to failure. As Medawar has stated the "tyranny of the skin graft in the inbred mouse" held back progress in organ grafting. Allografted skin does not behave like vascularised organs, and the controlled parameters of an inbred rodent strain do not resemble the immense variation of antigenicity and immunological response seen in man.

Much hope seemed justified when it was shown that antilymphocyte serum prepared in the rabbit against mouse lymphocytes would prevent the rejection of skin grafts from widely disparate donor strains and even from other species. Yet, many years after its first application to patients with kidney grafts, it is still not clear if antilymphocyte globulin (ALG) therapy adds significantly to the therapeutic index of Imuran and steroids; there is no doubt, however, that some batches of ALG can be dangerously toxic and can potentiate the risks of infection especially to viruses and fungi.

Tissue typing was another endeavour which seemed to have a bright future. A new and very complicated system of serologically defined antigens present on lymphocytes and many other tissues was discovered. They are certainly relevant to the outcome of graft survival. The genetics of this system and even the chromosome responsible have been demonstrated elegantly. Nevertheless complete matching of these tissue types in siblings only permits survival of skin grafts for some 20 days compared with 7 to 10 days when the grafts are mismatched. It is clear that there must be other important antigens that are not being detected, since the grafts are always rejected. Application of tissue typing to clinical kidney grafting has also been disappointing, except in grafts between siblings. If donor and recipient siblings are of identical tissue type, there is an 80% chance that the transplant will function normally after two years. Fully matched grafts between unrelated people do much better than unmatched grafts, but the influence of typing between unrelated donor and recipient when the match is only partial is weak, and most surgeons pay more attention to the clinical considerations and the quality of the organ than to the matching. Tissue typing and direct cross matching of recipient serum against donor cells is of importance in patients previously sensitised to transplantation antigens as a result of rejecting a previous graft, receiving blood transfusions or following pregnancy. Sensitised patients must receive a kidney from a donor to which he does not already possess heightened immunity, otherwise aggressive rejection is likely. As more transplantation antigens are defined by new techniques, tissue typing will become more relevant, but in practice the likelihood of finding a perfectly matched donor organ will become increasingly difficult.

Most workers have felt that the ideal form of immunosuppression would be specific only for the donor in question, so that the patient would not be subjected to increased risks of infection. Laboratory models of specific 'desensitisation' using transplantation antigen and antibody preparations have been described, but to date there has been little success in their clinical application. It may be necessary to monitor the reactivity of the recipient towards donor antigens in order to treat the patient with an effective 'recipe'. Such speculations are for the future, but it is important to remember that half of the patients receiving random, unmatched, unrelated cadaver kidneys do well and since the dosage of immunosuppressive agents can often be reduced to relatively safe maintenance levels, it is likely that these patients have come to terms with the graft antigens to allow for a peaceful and profitable co-existence that probably involves natural donor-specific unreactivity.

In spite of this static background, clinical organ grafting is a worthwhile form of medical treatment that is not yet available to many patients in need. To be dying from failure of a vital organ function is as serious an affliction as any other lethal disease. When we spend huge sums of money without question on the treatment of cancer and operating on the elderly, why should organ grafting be attacked so often as an expensive luxury? Since organ grafts are seldom successful in those over the age of 50, most patients in need are of potential economic value to the state. Dying slowly in an expensive hospital bed is likely to cost far more than a transplantation operation which, if successful, will restore a breadwinner or housewife to the community. These financial matters do not take into consideration the suffering of the patients and their relatives if they are denied treatment. In the United Kingdom there are approximately 3,000 deaths a year from kidney disease in people aged five to 55 years. The DHSS has established 25 dialysis and transplantation centres. Most of the dialysis spaces are full and new patients cannot receive treatment since only 500 kidney grafts a year are carried out. The majority of transplantation centres are performing less than half the number of grafts for which there are facilities. This is demoralising for the staff and patients, especially since the cause—namely a desperate shortage of donor kidneys—is potentially so easily soluble.

A kidney can be grafted from a live volunteer or a cadaver. Since the results of grafts from cadavers differ little from those obtained with grafts from unrelated live volunteers, only blood relatives are considered as donors. The operation for a live donor is not trivial and very often there is no suitable or willing familial donor. Removal of an organ from a dead body can do the deceased no harm and can be a gift of life to the recipient. Why then is there such a serious shortage? It has been suggested that in England the only thing more sacred than a live dog is a dead human body. This feeling for a cadaver may be an important subconscious reason for the lack of enthusiasm for organ donation after death. The precise details of what befalls a corpse are conveniently thrust out of conscious deliberation. Thus there has never been any serious opposition to the autopsy examinations ordered by coroners following most accidental deaths. The wishes of the deceased in his lifetime and those of his relatives have no bearing on the decision. All the organs are removed and examined, but these matters are not discussed by the relatives or the public. A request for organ donation does, however, require conscious thought on an unpleasant topic—death.

There are two categories of cadaver donor:

- Bodies brought into hospital dead. Here the diagnosis of death is straightforward, but there is urgency in removing the kidneys since if they are left in the corpse for more than an hour they will be useless. Once removed they are cooled and at 0 °C they can be kept in good condition for 12 hours. If they are perfused continuously with an appropriate cold oxygenated solution they can be preserved for up to 48 hours.

To comply with the Human Tissue Act of 1961, if the wishes of the deceased are known they are followed, otherwise the relative's permission must be sought. Often the relatives cannot be found in the limited time available. If they are traced it may be cruel to raise the question of organ donation at this moment of terrible distress; although sometimes this is not the case and the feeling that some good may result from their tragedy can give comfort. It is obviously preferable to know the wishes of the deceased—the simplest practical solution is to carry a kidney donor card as supplied by the Department of Health and Social Security. In spite of the fact that most people are in favour of organ donation after death, I doubt that more than a small percentage would carry a card, since it is a bother and its presence is a continuous *memento mori*.

- A body with a dead brain but an intact circulation, maintained by mechanical ventilator of the lungs. This category of cadaver donor is the only type from which heart or liver grafts can be used, because of their extreme vulnerability to ischaemic damage. After death of the brain, other organs and tissues die at different times depending on their oxygen requirements, unless the circulation is artificially maintained by oxygenating the lungs. Obviously all vital organ grafts must be alive, otherwise they would be useless to the recipients. The organs of a decapitated body could be perfused and oxygenated with the heart beating, yet no one would consider the individual to be alive. Nevertheless there is so much superstition and folklore concerning the heart that many people consider the beating heart to be the cardinal sign of life.

How can this view be reconciled with the fact that it is routine surgical practice in open heart operations to stop the heart so that it can be repaired? During this period the patient is kept alive because his brain is perfused by an artificial heart–lung machine. Should the cerebral circulation fail, the patient will certainly die. Patients with brain damage from an injury, haemorrhage or tumour are

Kidney Donor Card

Your kidneys could help someone to live after your death

Keep the card with you at all times in a place where it will be found quickly

THE Department of Health and Social Security has recently stepped up distribution of kidney donor cards like these. Four million have been distributed, and although this does not mean that a similar number have been completed, hospital authorities are finding that an increasing number of emergency cases, suitable for kidney transplant or research, are carrying the cards. Area health authorities are responsible for distribution, and the cards can usually be obtained from local hospitals.

I (full name)
request that my kidneys be used after my death for transplantation or, if they are found unsuitable, for research.

Signature of donor Date

The above-named person has discussed his/her wish with me and I do not object to that wish being complied with.

resuscitated and assessed. If the damage is severe they stop breathing and this function is taken over by a mechanical ventilator. If after careful examination by experienced neurologists or neurosurgeons it is established that the brain is totally and irreversibly destroyed, then the ventilator is stopped since the perfusion of a corpse can be of no benefit to the deceased and would cause distress to his relatives and the nursing staff.

The decision to stop the ventilator has absolutely nothing to do with organ grafting. This was an accepted humane procedure before organ grafting was established. Once the decision has been made, however, and if it is likely that the case may be a suitable organ donor, there is then time to discuss the matter unhurriedly and sympathetically with the relatives, and the transplantation team can be prepared. In the USA and several countries in Europe, the organs are removed before the ventilator is stopped, since the intact circulation will ensure that the organ is in perfect condition. In the UK organs are usually not removed until after the ventilator has been stopped and the circulation has ceased. The heart may beat for up to an hour without oxygen; during this period all the organs including the heart are suffering severe damage — since the blood passing through them is becoming progressively depleted in oxygen and nutrients and is becoming increasingly acidic.

The British Tranplantation Society recently published a report on the shortage of organs for transplantation, (*Brit. med. J.*, **1**, 251; 1975). It was concluded that apathy in the medical profession was the main cause of the shortage, but that this was aggravated by lack of public information, ambiguities in the law and an unhelpful attitude of some coroners. The report proposed that there should be minor changes in the law, and a code of practice to be followed by all transplantation centres.

Although the main clinical application of organ grafting has been the kidney, both the heart and the liver have been transplanted successfully and have restored moribund patients to normal lives. There are no substitutes for heart and liver function comparable with the artificial kidney. This lack of artificial organ support has held back progress. In spite of this handicap, Dr Shumway in Stanford has transplanted more than 70 hearts with results which are little inferior to those of kidney grafting. There are far more potentially suitable cadaver organ donors than are needed, but sufficient organs are unlikely to become available until it is assumed that after death it should be a routine procedure to remove organs for grafting. ☐

KENNETH MELLANBY

Paper chains

I FOUND the recent white paper *Food from Our Own Resources,* issued by the Minister of Agriculture, disappointing (Cmnd 6020, HMSO) It makes no provision for the possible effects of a fall in the value of the pound sterling, which would make it impossible for us to continue to import food at the present rate, nor does it suggest the action that would be needed if a world food shortage threatened our imports. It does, however, make modest proposals for increasing our agricultural productivity—by enlarging our dairy herd, increasing the acreage under cereals, and growing some oil seed. Even if all targets are met, we will still be far from self-sufficiency and (at present prices) our balance of payments deficit will still be enormous.

The White Paper does imply that a greater improvement in yield and in our finances may result from research. Those scientists remaining in agricultural research (and whose work, it is hoped, will have this result) may, however, be surprised to read that the "National reorganisation [of research] in line with Lord Rothschild's recommendations is already taking effect in the closer integration of research and development with agricultural progress." Although the precise meaning of this curious example of Whitehall prose may be difficult to disentangle, it presumably means that agricultural research is becoming more and more effective. The sad thing is that the writer of the White Paper probably believes that this is true.

It is perhaps too soon to analyse the total effect on research—and particularly on agricultural research—of the Rothschild system, but it is disconcerting to find that there is such a divergence of views between the actual researchers themselves, and the administrators and committee members concerned with scientific policy. In our laboratories we see the number of the scientists at the bench decrease, and find the vacancies of those who leave (often to move into administrative posts) remaining unfilled. Morale is lower than ever before, and complaints of time-wasting paper work, often at the behest of unnecessary committees, are widespread. Lord Rothschild criticised the research councils (to my mind, rightly) for wasting too much time and resources on committees, yet he has, no doubt unwittingly, caused the time spent on committees and working parties to be at least trebled.

The central feature of Lord Rothschild's proposals was the "contract". Money previously paid by the government to research councils has been transferred to executive departments who then pay the council for doing some particular piece of research. The idea was that this would make sure that work was concentrated where it was most needed. Now had contracts been the simple things suggested by Lord Rothschild, involving large sums to be spent on some wide field of work, the conditions simply and briefly set out on 'half a sheet of paper', the idea might have had some merit. But, unfortunately, the Civil Service has seen to it that many contracts are small, complicated and requiring the scientists involved to produce detailed 'project plans' and a constant flow of information to feed the computers which are playing an increasing part in sterilising originality at the laboratory bench.

The saddest result of all this administrative complication is that it has destroyed the enthusiasm of many research workers and has encouraged others to transfer to the administrative posts which seem to be so much more esteemed by the authorities. In the past, research for many was a way of life and workers often successfully chose problems which they believed were relevant and soluble. They were sometimes right, and they were then able to do much to see that their results were used, for instance, by the farmers. The trouble about the contract is that the scientist who has to carry it out may think it is for work which he cannot fully believe in. And he may well be right. But although in theory there are ways in which contractors can be persuaded to use their money wisely, few research workers believe that they will be very popular if they constantly shew that the authorities are incapable of selecting the best problems for investigation.

It is perhaps surprising that, though we have made many changes in the organisation of government-financed research in Britain, no one seems to have tried to find out how these have affected its efficiency. The impression certainly exists that no one is looking at all critically at the results of Lord Rothschild's recommendations. Surely someone should place a contract for such a study. ☐

international news

Out of sight out of mind?

from Vera Rich

PLANS are in hand for a permanent international organisation to be set up to investigate reports of "psychiatric inquisition" (the abuse of psychiatry for political ends) and to take appropriate measures to condemn and prevent such abuses. This is the chief outcome of a symposium on "Medical ethics and abuses of psychiatry for political ends", held in Geneva on April 19, under the auspices of Amnesty International.

After the presentation of case histories of such abuses, and extensive discussions of the moral, juridical and social issues involved, the symposium resolved to set up an initiative committee leading to the establishment of the proposed international organisation. It also appealed to "all medical associations and conferences not to hesitate, in spite of the threats of withdrawal by member countries, [to condemn] explicitly these abuses of psychiatry and to boycott doctors and organisations who lend themselves to them and who refuse commissions of enquiry".

The problem of psychiatric abuse was carefully distinguished from the "errors and cases of negligence" which occasionally occur in any country or system. The symposium was concerned with interventions by a political system to use (or abuse) psychiatry to serve its own ends, by detaining in mental institutions critics of the regime, whose views are considered "at one and the same time, to be both symptom and proof of mental illness", and the use of allegedly curative procedures as a means of political repression.

Although it was stressed in the opening speech that, in accordance with the aims of Amnesty International, the symposium was of an a political and humanitarian nature, the case histories and evidence presented all related to the Soviet Union, since it is from there that most of the evidence comes, both as regards the number of persons concerned and the sophistication of the techniques used. Two former detainees of this kind, Viktor Fainberg and Viktor Nekrasov, spoke of their own experiences in Soviet penal psychiatric institutions. Another Speaker, Dr Marina Voikhanskaya, who was allowed to emigrate from the Soviet Union only a fortnight before, spoke of her own experience as a psychiatrist in a Leningrad hospital, where she had refused to permit the punitive administration of drugs to dissidents temporarily confined there, en route to or from a penal psychiatric institution.

Voikhanskaya and Fainberg: released

The picture she gave was essentially one of a conspiracy of silence. She herself had been practising as a psychiatrist for almost ten years before she came by chance into contact with one such dissident detainee—the artist Ivanov. When she attempted to make further enquiries about such cases she found on the one hand obstruction from hospital authorities and on the other a pusillanimous attitude from fellow psychiatrists, "who did not want to know about such matters". She managed, over the course of four years, to build up a fairly comprehensive picture of the certification of dissidents, under such diagnoses as "creeping schizophrenia", or "reformist tendencies". 'Treatment' in such cases included close confinement, tying the "patient" to his bed for several days "with the neglect of the elementary rules of sanitation", and the administration of massive doses of drugs, notably haloperidol, which would not be justified even had the original diagnosis been correct. Attempts to break through this barrier of silence by Dr Semeon Gluzman and Vladimir Bukovskii, who tried to inform public opinion abroad and (by way of the *samizdat* network) within the Soviet Union, earned them heavy prison sentences. Dr Voikhanskaya stressed that such abuses affect not only the status of psychiatry within the Soviet Union, but the "honour of the entire psychiatric profession".

Yet so long as the penal psychiatric institution remains a useful oubliette for dissidents, there exists the tragic possibility that what was originally a paper diagnosis for political reasons may become, under 'therapy', the simple truth. This, it would seem, is the fate of the Ukrainian mathematician Leonid Plyushch. Since his arrest in 1972 he has spent a year in prison and more than two years in the "Dnepropetrovsk special" (penal) psychiatric institution. According to his wife, Tatiana, Plyushch entered the hospital a sane man and is under the course of intensive treatment, with ever increasing doses of drugs. He suffers petty but cumulatively distressing harassments, and is rapidly deteriorating intellectually and emotionally. "The mathematician Plyushch", she writes, "the Leonid Plyushch known to me, to his children, relatives and friends, this Leonid Plyushch no longer exists. There is an exhausted man, driven to the last brink of suffering, losing his memory, and his ability to read, write, think . . . "

Dr Voikhanskaya characterised the purpose of the 'psychiatric inquisition' as two-fold: the long-term removal from circulation of those who steadfastly maintain views which oppose the established order, and the discrediting of those views among those who, not knowing the dissident personally, may well believe that a diagnosis pronounced by some eminent doctor cannot be entirely unfounded. The case of Leonid Plyushch, however, indicates a further outcome; the dissident, once confined and subjected to treatment prescribed for political not medical reasons, may well deteriorate into a condition of genuine psychological illness—that once out of sight in a suitable institution, he may well become, not only legally but also in fact, 'out of mind'. ☐

Satellites over the oceans

from Angela Croome

THERE have been several moves in recent years to have marine communications carried out by satellites—either of the active type, for navigational purposes, or as passive relays to improve safety services and routing operations. The most developed initiative has come from IMCO, the International Maritime Consultative Organisation, an agency of the United Nations, which is at present holding a 2½-week international conference at its London headquarters aimed at setting up an international maritime satellite executive organisation — INMARSAT — to bring about such a system by the end of the decade.

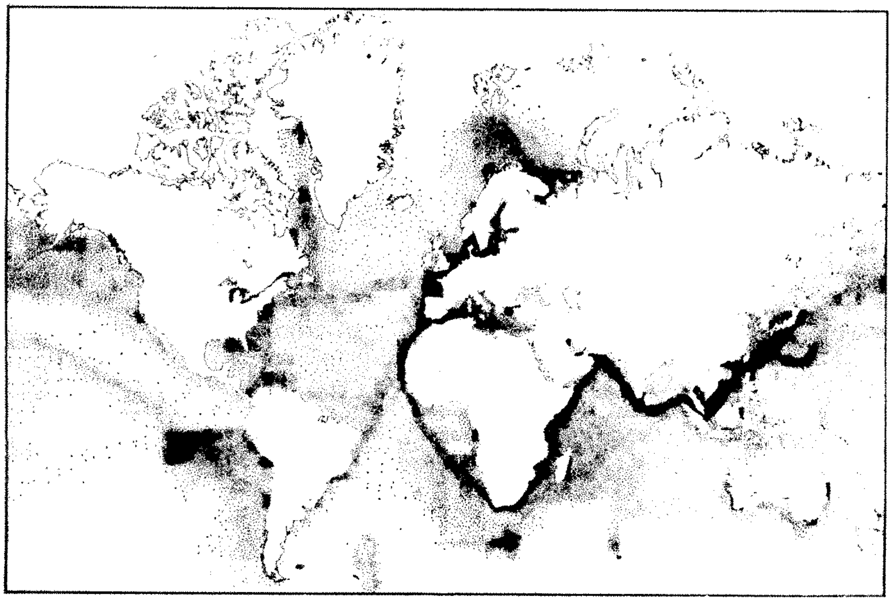
There are a number of reasons for favouring a transfer of ship-shore and ship-ship communications to satellites. Traffic statistics of coast stations reveal that demands for long range h.f. communications, and particularly radiotelephones, are steadily increasing; saturation of existing facilities is expected by 1980. (At some times of day this is already the case.) The size and number of the world's commercial fleet is also going up exponentially—6,000 vessels over 10,000 tons in 1970 against an estimated 60,000 in 1980—and this will add to the overload. The present average delay in international h.f. telegraph traffic is six hours with delays of 12 hours being not uncommon—hardly satisfactory when an emergency occurs. The present scarcity of ships' radio officers today (typically there is only one aboard) means an 8-hour watch which may not coincide with the times of best radio propagation. The vagaries of ionospheric propagation introduce radio blackouts, interference and fading which further limit effective radio time and traffic.

The International Marine Consultative Organisation began considering the possibilities of a switch to satellite communications for ships at sea in 1966. In 1971 frequencies were set aside for the use of maritime satellites by the international radio authorities, and in 1972 a Panel of Experts was set up by IMCO to look at the characteristics and operational requirements of a "maritime mobile satellite system". This met six times and the experts' report—136 pages of it—is the principal document for discussion at the present conference. Its main conclusion is that there is "an urgent need" for satellite communications for shipping and that such a system should concentrate on general communications requirements to handle distress, safety and public correspondence. Radio determination of a ship's position is feasible and attractive but of less priority. The report stresses that a marine satellite system would only be effective and economic if it could carry out more than one function, preferably "as many as possible".

The report considers in some detail the technical requirements of the system, whether it could be combined with the projected aeronautical mobile programme (Aerosat), the economics and a timetable. It comes out in favour of a three-synchronous-satellite system (which could cover all but 20% of shipping) and costs are based on the use of a Thor-Delta launcher. If the report is adopted by the conference there is a Draft Convention appended to bring the new INMARSAT organisation into being. Consideration was given to using the Intelsat organisation (the authority for the existing world satellite communications network) but the poor representation of some of the major shipping countries in Intelsat militates against this. All countries must accept the INMARSAT system it is stressed, because safety at sea cannot be partial.

The US delegation introduced a note of disharmony in advance of the conference, and has been the sole IMCO member to reserve its position on the report. The USA has put on the record that "the establishment of a new international organisation is likely to pose problems . . . leading to serious delays"; it finds inadequacies in the proposed draft agreement and in the economic review (which does not include a cost-benefit analysis) and has doubts that the reliability of ship terminal equipment has been fully investigated. ☐

Map showing the distribution of merchant shipping expected by 1980.



Getty hands out cash

MR JOHN PAUL GETTY, the octogenarian oil millionaire, has set up a $50,000 wildlife conservation prize and is so pleased with the first award that he is now offering it for a second year. The first John Paul Getty Award for Wildlife Conservation was recently presented (at the White House) to the colourful Peruvian, Felipe Benavides, better known as "Mr Vicuna". He has been largely responsible for saving the remaining vicunas of the Andes from extinction and has now established a reserve for them in their native habitat where there are hopes that they may become semi-domesticated. Benavides has transferred the whole of his prize money to running the Paracas Reserve. When not saving the vicuna (and he is now pressing for a ban on whaling within the 200-mile zone of Peruvian waters) Benavides is a business man, and a rather special one since he has the capacity to remain influential whatever the current complexion of Peruvian politics.

Mr Getty is anxious to gain the widest number of candidates for the second award of his $50,000 prize. More than 500 people applied for the first. The fact that Commandant Cousteau was invited to speak at the announcement of this year's award rather suggests that there is an interest in finding a candidate active in marine conservation. The jury for the award (which is chaired by HRH Prince Bernhard of the Netherlands) has been cunningly chosen from the best known figures in conservation including Sir Peter Scott and Cousteau himself, which forces a search for new faces and names in this field. Nevertheless there is a certain irony over the application of this money to foster marine conservation in view of the damage done to sea birds and other marine life by oil spills; it is one that Mr Getty half-acknowledged at his reception. ☐

SIR Frederick Dainton, Chairman of the University Grants Committee (UGC), was among friends last week when giving evidence to the Science Sub-committee of the Commons Select Committee on Science and Technology. No one disputed that he had real problems and no one seemed disposed to pick a quarrel with him over the way he was trying to keep university finances going. Sir Fred warned in his written evidence that the equilibrium of the dual system was in some difficulty because the erosion of UGC support for the base had been more rapid in the past year or so than erosion of funding for the research councils.

The UGC's problem is fairly simple: serious failure to keep up with inflation. If the government chooses to do so it may scale up grants for inflation using the university costs index; but the index is retrospective—inflation for last year decides this year's scaling up. The index rose 10.7% in 1973 and 29.4% in 1974 and the UGC was faced with two dilemmas: first, that the acceleration in inflation could not be reflected in disbursements during 1974–75 and second, that the government was not even disposed to allow the 10.7% to go through (academic salaries, comprising half of UGC grants, were properly supplemented). The £187.5 million for general purposes was eventually supplemented by £19 million but the shortfall to universities in the year 1974–75 has been £35.4 million. The recent settlement for 1975–76 allows for inflation in 1975, but the £35 million is lost forever

The consequences of present shortfalls are all too obvious—every university tries to maintain its teaching standards, so research facilities suffer. There are twelve new university libraries planned, but none as yet has a chance of being funded. There are no plans for new science and technology buildings; few staff are being replaced when they leave; and exacerbating all this is the lack of any planning horizon If universities could not know whether there was worse to come, they would go on freezing hiring, and Sir Fred, wearing his *quondam* vice-chancellor's hat, said he could not blame them.

To all of this the committee lent a sympathetic ear—not that there is much more they can do. Only two suggestions disturbed the gloomy tranquillity. Is there any redundant research going on, asked Mr Anthony Nelson—anything coming to the end of its usefulness? Sir Fred was cagey, certainly not everything was equally useful and equally high powered intellectually, but it was not his job to evaluate. Then would you welcome a new body of scrutineers to pinpoint redundant research? No thanks, there have been enough disturbances recently what with Lord Rothschild's report and the economic crisis: such a body in the past would probably have voted to terminate support for Kipping or Fleming. And then Mr Norman Tebbitt (not for the first time) raised the issue of whether postgraduate students from overseas were paying their way. Difficult, said Sir Fred, and I don't fix the fees, but there was a case for increasing charges. The trouble was that international links often returned intangible benefits.

Round Britain

Ironically the only thing working in the UGC's financial favour at present is the disinclination of young people to go to university. Projections for the year 1975–76 are now that there will only be 270,000 students in universities —36,000 less than had been planned for. That is hardly a saving for which the UGC can be grateful.

● The seven largest contract research organisations in the UK are banding together to form an association (AICRO) which they hope will help them to tap new markets and expand old ones.

Income of AICRO members in 1974

Company	£ million
Electrical Research Association	1.300
Fulmer Research Institute	1.060
Huntingdon Research Centre	4.445
International Research and Development	1.500
Inveresk Research International	0.750
Ricardo Consulting Engineers	2.109
Robertson Research International	2.106

Launching the new association last week, its first president, Mr D. Downs, of Ricardo Consulting Engineers, said that the body would have two principal tasks during its first year of existence. First, it would set out to convince government departments of the advantages of having research done by independent organisations — chiefly value for money and efficiency. The association thinks, for example, that the research requirements' boards set up in government departments in the aftermath of the Rothschild report should be less insular and more prepared to let research contracts on the open-tender principle, as is the case in the USA.

Second, AICRO will be looking hard at opportunities abroad, not only in the USA, where it feels its members can "respond cooperatively" in the face of competition from giants like Battelle, Arthur D. Little and the Mitre Corporation, but also in Europe. AICRO hopes eventually to have permanent outposts in Brussels and Washington to ensure that no opportunities are missed.

Although the association is a 'trade association' and in no sense an amalgamation of the seven companies, the terms under which it has been set up include a provision that *ad hoc* consortia shall be formed from time to time as circumstances demand.

● In his introduction to the 1974 report on research and development carried out by the Ministry of Agriculture, the Chief Scientist, Dr H. C. Pereira, stresses the need for Britain to become more self-sufficient in food.

A vastly improved programme of grassland management is one of the top priorities on the lists of projects which could help to bring about this self-sufficiency. Animal feeding stuffs, imported from abroad, have increased rapidly in price over the past few years, and the idea of feeding British livestock from our own land has now become much more attractive economically. Work which the ministry is supporting, either in its own establishments or through commissions to the Agricultural Research Council (ARC) includes improved management of hill grazing lands and the breeding of varieties of grasses and forage legumes suited to this marginal grazing land.

Advanced techniques of field-wilting and barn drying of hay, and of pressure-dewatering of crops of grasses and legumes before they are dried will be applied to most of the forage harvested rather than, as at present, to only a small proportion under advanced management The need for a drastic change in feeding policies for both beef and dairy cattle is evident, says the report, from the overall food supply data for the UK. Measured on the basis of protein intake, the UK carries a feeding burden almost 4½ times that required for its human population of 56 million.

Dr Pereira also forecasts a 'green revolution' for British cereal growing, after the introduction of the new highly productive soft wheats such as Maris Huntsman, bred at the ARC's Plant Breeding Institute at Cambridge, which has achieved on-the-farm-yields of 4 tons an acre, as opposed to the national average yield of 35 hundredweights an acre. Increased demand for home-grown cereals may result in the spread of cereal growing into the wetter areas of Britain, not ideally suited to these crops. This will bring problems of greater susceptibility to disease, and the assessment of cereal foot and root rots—a relatively little worked field of research—has been proposed by the ministry's Plant Pathology Laboratory.

Evolving evolution

SIR,—A science writer who spends his life recording the repeated triumphs of unorthodoxy must complain about the tone of R. A. Crowson's remarks on molecular evolution and anti-Darwinism (*Nature*, **254**, 464; 1975). The simplest fault is the most telling: throughout his attack on Ohta, Crowson refers to "him"—but Ohta is a woman. That is a symptom of the lack of ordinary personal communication between the "neutralists" and "selectionists".

There is a lack of scientific communication, too. Crowson makes much of alleged discrepancies between the fossil record and the dates used by Dickerson and by Wilson *et al.* in their molecular chronologies. As Dickerson himself pointed out forcibly: "The zoologists who have the best command of information on dates have maintained a reserved scepticism towards the entire protein endeavour."

The language Crowson uses is improper for a scientific argument. Concerning his quotation on "the demons of the underworld, chance and probability", one wonders where physicists would be today had they shunned those demons and looked only to "the heavenly powers"? Most perturbing is his phrase "potentially dangerous to our science", applied to the work of Kimura, Ohta and others. Dangerous to whom? To a biological Establishment unwilling to rewrite its lecture notes? If science does not live dangerously, open always to rebuttal and revision, it quickly ceases to be science.

Neo-Darwinism has shown signs of hardening into quasi-religious dogma of a kind that Darwin would surely have repudiated; witness Crowson's phrase about "the historic truths of evolution". Fortunately, discoveries and ideas have kept the blood circulating, not only the puzzling intraspecific and interspecific variations in molecular structure but, in a quite different direction, the violation of the canon against group selection in explanations of social behaviour.

I don't know whether the "neutralists" are correct or not, but then no one does. What I do observe is that some of the critics of Kimura and Ohta react like priests scenting blasphemy. Which really is "dangerous to our science": bold hypotheses which eventually can be thrown out if wrong, or theories too sacred to question?

Butterflies lost

SIR,—In 1974 about 15 butterflies were stolen from the Museum National d'Histoire Naturelle in Paris. All the specimens were rare and beautiful *Ornithoptera* and *Papilio*. The museum is understandably anxious to trace their whereabouts and puts their value at 30,000 francs (about £3,000).

Butterflies, it seems, are nowadays treated like postage stamps. Rare and beautiful tropical species are in great demand, and on a world basis the buying and selling (and stealing) of specimens is a growth industry. There are big dealers in many countries, particularly in the United States and Japan but also in Britain, and there are numerous smaller dealers and 'contacts' in tropical countries. For many years Taiwan has been at the centre of the trade, and business in Brazil is said to amount to 50 million specimens a year. The demand is almost exclusively for large and showy species. The wings are often made into jewellery (cufflinks, brooches and rings) or are used to decorate trays.

Hardly anything is known of the size of butterfly populations or if species are endangered by massive exploitation for profit; few countries have laws that restrict the import and export of specimens. Years ago the birds of paradise and other beautiful and exotic birds were brought to the verge of extinction by collectors and dealers, but legislation was eventually introduced and it is not easy nowadays to trade in them. Must we wait until some of the most beautiful creatures on Earth are nearly extinct before we take steps to stop the trade?

Nitrogen fixation

SIR,—Current biochemical and genetic attempts to develop nitrogen-fixing bacteria symbiotic with plants now lacking them (some described by John Postgate, *Nature*, January 31, p. 305) raise a significant question.

Sir Peter Medawar has said that when developing a new technology, one should try to imagine the consequences if one succeeded beyond one's wildest dreams. Suppose we developed efficient, enthusiastic, and promiscuous nitrogen-fixing bacteria which, rather than confining their attention to a few agricultural crops in specific areas, became widespread in distribution and in effect on the planetary nitrogen cycle. What then?

Those of us who respect the extensive design experience reflected in present arrangements for fixing nitrogen—even more than we respect man's ingenuity in altering them—might rephrase the question more simply. If some plants are not now leguminous might there not be a reason for it? If there were a better kind of nitrogen cycle, would it not already be here?

Citation

SIR,—Cawkell (April 3) defends citation analysis largely on the grounds that through repeated co-citation groups of articles come to be "the putative 'core' literature of the subject".

With my youthful idealisms now los in the mists of time I regard repeated co-citations with suspicion if not with cynicism. Here I find myself in sympathy with E. Chargaff (*Nature*, **248** 776–779; 1974). He expressed the view that bibliographies were once comparatively honest but that there is a growing tendency for groups of references to be 'lifted' from one publication to the next. The growth of the scientific literature is such that it is difficult for an author to be fully conversant with the content of all articles that may have a bearing on his work. The citing o papers that have not been read cannot however, be condoned; it leads not only to spurious 'cores' (well exemplified in my own field of study) but also to spurious reputations. A citation should imply an author's personal opinion on the relevance of the cited publication.

'Enigma Variations' of mammalian messenger RNA

from Beverly Griffin

THE significance of the sequences of the 3′-end of messenger RNAs in mammalian cells has for the past few years been a problem for cell biologists. Most messenger RNAs isolated from the cytoplasm of eukaryotic cells have been found to contain polyadenylic acid sequences of varying lengths at their 3′-ends. Attempted explanations for the function of the 3′-terminal poly (A) residues have had to take into account the fact that although most eukaryotic messenger RNAs contain them, not all do (*Nature*, **252**, 268; 1974). Now, before the significance of the unusual nature of the 3′-end of many messenger RNAs has been clarified, attention has been re-directed to the 5′-ends of these molecules by the discovery that they also have unusual nucleotide sequences.

Rottman, Shatkin and Perry (*Cell*, **3**, 197; 1974) described a nucleotide sequence at the 5′-terminus of a wide variety of messenger RNAs, which consisted of 7-methylguanosine linked through its 5′-hydroxyl group *via* a tri-(or pyro)-phosphate group to the 5′-hydroxyl of an O-methylated nucleoside. Although these authors gave a chemically incorrect structure to 7-methylguanosine, it seems nonetheless that their general ideas about the structure of the 5′-ends of eukaryotic messenger RNAs may be correct. A similar kind of structure at the 5′-ends of several low molecular weight nuclear RNAs of Novikoff hepatoma ascites cells had also been reported in an abstract by Ro-Choi *et al.* (*Fedn Proc*, **33**, 1548; 1974). Between them, these two reports have stimulated a great deal of research.

Three papers in this issue of *Nature* by Muthukrishnan, Both, Furuichi and Shakin (**255**, 33; 1975), by Abraham, Rhodes and Banerjee (**255**, 37; 1975) and by Adams and Cory (**255**, 28; 1975) discuss the blocked (or capped) 5′-ends of messenger RNA from two viruses (reovirus and vesicular stomatitis virus (VS)) and from rabbit reticulocyte and mouse myeloma cells In all three papers, 7-methylguanosine has been shown to be the nucleoside used by the cell as a block for the 5′-tri-(or pyro)-phosphate end of the messenger RNA. This is linked to an O-methyl nucleoside which may apparently be one of any of the four bases. It is postulated here (as in the transfer RNAs) that O-methylation may serve to protect the phosphodiester link of messenger RNA from the nuclease activities in the cell, with the protected nucleoside possibly playing an important rôle during the processing of the messenger. Similar results are now appearing, or will shortly appear, in the literature about the 5′-ends of other messenger RNAs, not only from viruses whose genomic and messenger information reside in the same molecules (reovirus, Furuichi *et al*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 362, 742; 1975, and silkworm cytoplasmic polyhedrosis virus, Furuichi and Miura, *Nature*, **253**, 374; 1975), but also in viruses containing DNA as their genomes (vaccinia virus, Wei and Moss, *Proc. natn Acad. Sci. U.S.A.*, **72**, 318; 1975 and Urushibara *et al.*, *FEBS Lett.*, **49**, 385; 1975, Simian virus 40, Lavi and Shatkin, *Fedn Proc.*, **34**, 526; 1975, and adenovirus, see Muthukrishnan *et al.*), and in uninfected cells (including mouse L cells, monkey BSC-1 cells and HeLa cells, see Muthukrishnan *et al.*) The weight of the evidence suggests in fact that methylated blocked 5′-termini may prove to be a general feature of eukaryotic messenger RNAs.

Thus, before a biological explanation has been found for the nature of the 3′-end of mammalian messenger RNAs, a biological explanation must also be sought for the nature of the 5′-end. Some progress has already been made on the rôle of the structure at the 5′-end, notably by the group at the Roche Institute of Molecular Biology (Muthukrishnan *et al.*, page 33, and Both, Banerjee and Shatkin, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1189; 1975). They show first that methylated reovirus and VSV messenger RNAs stimulate protein synthesis (in wheat germ or mouse L cell protein synthesising systems) to a greater extent than unmethylated messenger RNAs. They also show that messengers synthesised *in vitro* in the presence of S-adenosylmethionine by virion-associated RNA polymerases contain the 5′-terminal structures found *in vivo*, and moreover that the *in vitro* synthesised messengers are translated with fidelity in the protein synthesising system. Their conclusions from these, and studies carried out with aurintricarboxylic acid (which inhibits polypeptide chain initiation) and sparsomysin (which inhibits chain elongation), are that methylation (at least with reovirus and VSV) is required for translation and probably occurs at the initiation step of protein synthesis. They do not exclude the possibility that 5′-terminal methylation is also important in the processing of eukaryotic messenger RNA.

None of the studies to date offers any explanation for the choice of 7-methylguanosine as the blocking group for the 5′-end of mammalian messenger RNA. The guanosine may be added to the 5′-end of the RNA by guanosine triphosphate, and this may in part explain the need for GTP in protein synthesis. Guanosine may then be methylated at N–7 by the machinery of the cell. (It is noteworthy that all the chemical studies on methylation of nucleosides show the high susceptibility of the 7-position of guanosine to methylation.) 7-methylguanosine, moreover, is a highly polar molecule at every *p*H at which it can be studied, and has never been isolated except in a hydrated state. Thus, this modified base on a messenger RNA would be expected not only to increase the hydrophilic nature of the macromolecule, but also to help it to form stable salt bridges in, for example, a protein-nucleic acid interaction complex.

Finally, it is conceivable that the blue fluorescence associated with 7-methylguanosine at *p*H 7 (Hendler *et al.*, *Biochemistry*, **9**, 4141; 1970) could be used as an assay for locating and purifying messenger RNAs. This marker might prove of value particularly in messengers lacking the 3′-poly (A) end (where the usual affinity chromatography procedures cannot be used for separating messenger from the bulk of other large cellular RNA molecules).

There seems little doubt that the finding of unusual sequences at the 5′-ends of eukaryotic messenger RNAs will prove a considerable stimulus to research, and may prove to be more illuminating than complicating.

Ecology of human parasites

from Robert M. May

ECOLOGICAL aspects of the relation between humans and their various parasites and pathogens is receiving an increasing amount of attention.

David Bradley (in a chapter in *Ecological Stability*, edit. by M. B. Usher and M. H. Williamson; Chapman and Hall, 1974) has recently drawn together some of this theoretical work and field observation. He distinguishes three types of mechanism whereby parasite populations may be maintained. In the first, parasite populations are determined primarily by the transmission phase. Because transmission depends on the varying environment, this makes for widely fluctuating or 'unstable' populations. This first general mechanism has received much attention in the classical parasitology literature; it invites comparison with other animal populations regulated mainly by "density independent" factors. The second type of parasite density regulation is tied to the host population level, which itself depends on that of the parasite (either through mortality, or the development of complete immunity). This density dependent regulatory mechanism makes for a degree of stability in the parasite population, but remains precariously dependent on the size and structure of a particular host community. The third and most stable mechanism involves parasite regulation by the individual hosts. The parasites in effect use the host's immune system to protect themselves against competition, and maintain infection at a steady but sublethal level: if a helminth has a usual transmission rate of 100 worms inoculated into each host, and the host has a means of preventing the worm load rising above 10, then a tenfold decrease or indefinite increase in transmission of parasites will leave the system unaffected.

This is the ultimate in regulation, and is seen to a varying degree in many parasite systems. Work by Smithers (*Br. med. Bull.*, **28**, 49–54; 1972) and others show that, in Rhesus monkeys infected with *Schistosoma mansoni*, adult worms induce antibody production, which kills or inhibits the growth of subsequent young schistosomes. Thus challenge infections are unsuccessful, while the initial infection persists, continuing its egg production. McCullough and Bradley (*Trans. R. Soc. trop. Med. Hyg.*, **67**, 475–490; 1973) and others have gathered epidemiological evidence suggesting that such a mechanism operates in some human populations infected with *Schistosoma haematobium*, the cause of urinary bilharziasis.

These ecological aspects of the way parasites regulate their populations—by transmission, by overall host population levels, or by host individuals—clearly have implications for public health strategies. If transmission is the key link, then a relatively simple strategy of chemical warfare against the intermediate host (mosquitoes, snails, and so on) is likely to succeed. Conversely, parasites which have evolved stable levels of infection with their hosts can remain essentially unaffected by such a strategy. A clear example comes from Lagos in Nigeria, where a vigorous campaign succeeded in reducing the anopheline mosquito to less than 2% of its previous level, but where the effect on human malaria was very slight. Similarly, in a highly buffered system such as the schistosome–human host relation, a reduction in the intermediate host snail population by one or two orders of magnitude could well have little effect on the prevalence of the infection.

Vaccination against malaria provides another example where ecological theory marches with public health data. Cox (*Nature*, **252**, 268; 1974) has summarised medical evidence to the effect that (at least in monkeys) vaccines can induce not only strong protection against the homologous human malaria species, but also a degree of immunity against heterologous species. Joel Cohen (*Q Rev. Biol*, **48**, 467–489, 1973) observed that, to malaria species colonising a human, "each man is an island, John Donne notwithstanding": thus ecological notions as to the dynamics of island colonisation may be relevant. Such theories would predict an interaction among the species of human malaria, and Cohen surveyed a wealth of data in support of this conclusion. Such theoretical and empirical arguments for a degree of heterologous immunity have obvious practical importance: they suggest that a malaria vaccine need not be specific to each of the species, strains or antigenic variants of *Plasmodium* in order to be effective.

Chemistry should broaden the mind

from J. N Lazonby

The Annual Chemical Congress was held at the University of York on April 7–11. The theme of the congress was 'a view towards the 21st century' and the education symposium reported here dealt in particular with problems of innovation.

"WHY talk about overproduction of chemists?" asked Lord James of Rusholme in his lecture entitled: 'Education through Chemistry?'. "Chemistry courses have been associated too much with vocational rather than educational aspects We must make greater claims for chemistry as an intellectual discipline and place less emphasis on industrial applications and vocational training. Undergraduate chemists must cease to think of themselves solely in terms of future chemists." Lord James saw a PhD as a highly valuable stage in the educational process and not as a final commitment to chemistry.

This viewpoint provided a sharp contrast with the previous lecture given by J. Blears (University of Liverpool), who discussed the supply of chemistry graduates in relation to the needs of industry. He pinpointed the coincidence of the expansion of university science departments with the decline in the proportion of the gross national product being spent on research and development. He suggested that the chemical industry is now sufficiently mature that the need is for economic optimisation of production, rather than for innovation. Thus, from this point of view and also in comparison with other countries, such as the USA, it would seem that we are producing enough first degree chemists and possibly over-producing PhDs for the research and development needs of industry.

R O. C. Norman (University of York) pointed out that universities are good at keeping abreast with the development of subject matter, but there is still much to be done to enhance the educational value (as stressed by Lord James) of chemistry courses. Designers of courses must be more conscious of the qualities of mind which ought to be inculcated. Chemistry courses are good at developing numeracy, but do they develop judgement or verbal skills? Chemistry involves judgement, but students are often not allowed to practise judgement until they are doing research. In particular, he thought that the role of practical work at university ought to be examined more closely. In this respect, he welcomed the University of Sussex 'degree by thesis' as an interesting and worthwhile innovation from which much would be learnt.

Professor Norman stressed that a variety of courses must be provided, ranging from those which are suitable for the future professional chemist to those which offer a study of chemistry in a wider context. But he felt that universities ought not to over-react to student demand and introduce many new courses such as environmental sciences as such aspects may, more sensibly, be absorbed within existing science courses.

The general mood of the speakers on this first day of the symposium was that innovation at all levels of chemical education ought to place greater emphasis on the educational value of courses in terms of the intellectual skills and attitudes which they ought to develop. Also a more liberal attitude ought to be encouraged towards the types of future employment for which chemistry graduates are suited and, as B. M. Kingston (University of Edinburgh) pointed out in his talk, the chemical industry must accept the responsibility of steady recruitment. It was felt that such measures would secure the place of chemistry in the educational system.

The highlight of the second day was undoubtedly the lecture given by J. A. Campbell (Harvey Mudd College, California). He spoke about the CHEM Study project, which, with its stress on a practical approach, has been a major innovation in secondary level chemical education in America. His talk marked the inauguration of joint meetings between the Education Division and the Chemical Education Section of the American Chemical Society. In a most entertaining and stimulating lecture, he accounted for the project's national and international success as indicated by the large scale adoption of the materials. Professor Campbell stressed that the CHEM Study had not been expected to solve all the problems and that its main aim had been to cause 'movement' in chemical education at the secondary level, and it is in this respect that the project has been most successful.

Interplanetary dust cloud

from David W. Hughes

ONE of the main problems in understanding the nature of the interplanetary dust cloud is that most of the observations are made on or near the planet Earth which is stuck in the ecliptic plane at 1 AU from the Sun. If all the orbital parameters of the dust particle can be measured these can then be extrapolated backwards in time and with care a spatial distribution of particles can be built up. But the resulting dust cloud models obtained by different researchers differ widely The value of the density, ρ, of the cloud at 1 AU is about 1.5×10^{-22} g cm^{-3}. Its variation with distance from the Sun, r, is under considerable debate. Calculations have produced ρ=constant ($0<r<3.5$ AU), $\rho\propto r^{-1}$, $\rho\propto r^{-1.5}$ and $\rho\propto r^{-2.5}$, ample proof of the present confusion.

Luckily interplanetary space probes have come to the rescue: one easy way out of the dilemma is to measure ρ using detectors on Mariner and Pioneer spacecraft as they travel towards Mercury and Jupiter. Rhee, Berg and Richardson (Goddard Space Flight Center, Greenbelt) report the results in a recent article in *Geophysics Research Letters* (**1**, 345; 1974). They find that the spatial density of particles with mass greater than 10^{-13} g is independent of heliocentric distance between 0.75 and 1.09 AU and that there is no enhancement around 1 AU. This result agrees with the Mariner II and IV data analysed by Alexander, McCracken and Bohn (*Science*, **149**, 1240; 1965) who found ρ constant between 0.72 and 1.56 AU.

Going further out, data from penetration cells on board Pioneer 10 and 11 indicate that the density varies as r^{-1} from 1 AU out to Jupiter's orbit, this experiment however having a mass threshold of 10^{-9} g. Alvarez, Humes, Kinard and O'Neal (NASA Langley Research Center) reported these results at the 1974 COSPAR meeting. They also found a peculiar Kirkwood-type gap in the dust cloud between 1.16 and 1.35. AU and a two order of magnitude increase in the dust density near Jupiter.

Looking at still larger particles (diameter 35 μm to 10 cm) Soberman, Neste and Lichtenfeld (General Electric Space Science Laboratories, Philadelphia) found $\rho\propto r^{-1.7}$ for the smallest to $\rho\propto r^{-3.2}$ for the largest. Using photometers on the same spacecraft (Pioneer 10) the zodiacal light brightness was found to vary as r^{-2} out to 2.25 AU and then to decrease more rapidly (1974 COSPAR meeting).

Obviously the problem is far from simple, with the variation in spatial density being a function of particle size (this is clearly seen when considering asteroidal sized particles at one extreme and solar wind particles at the other). It also seems a shame that Mariner 10 did not carry a particle-detecting experiment on its way to Mercury because extending the data into 0.3 AU would be very useful. The results from the recently launched West German–US solar probe Helios A which goes in this far will be awaited with great interest.

Very deep fault planes?

from Peter J. Smith

ALTHOUGH earthquakes are being studied ever more intensively, the physical mechanism of deep events still remains uncertain. The patterns of first motions and amplitudes of P and S waves radiated from deep shocks suggest strongly that the double-couple component of the source mechanism dominates other components, but the proposition that the double-couple results from shear dislocation along a fault plane is less easy to substantiate. Moreover, there are other possibilities to consider. Evison (*Bull. seism. Soc. Am.*, **53**, 873; 1963), for example, suggested that deep earthquakes may be produced by rapid phase transitions; and models involving changes of state throughout a finite volume were later analysed by Knopoff and Randall (*J. geophys. Res.*, **75**, 4957; 1970).

Nevertheless, Fukao (*Bull. Earthq. Res. Inst.*, **48**, 707; 1970) and others came down in favour of the more traditional explanation (in spite of the difficulty of envisaging fault motion at great depth) on the basis of their studies of azimuthal variations of the duration of P and S pulses. Even more direct evidence was obtained by Oike (*Bull. Disast. Prev. Res. Inst., Kyoto Univ.*, **21**, 153; 1971) and others who found that some deep events closely related in both space and time lie along a plane roughly coincident with a nodal plane of the focal mechanism solution for one of the events.

The difficulty in attempting to locate possible deep fault planes by observing the spatial distribution of deep earthquakes is that foci must be determined very accurately. In a new study of deep (~600 km) events in the northern part of the Tonga Island Arc, Billington and Isacks (*Geophys. Res. Lett.*, **2**, 62; 1975) have therefore used the method of Joint Hypocenter Determination (JHD) —a method developed by Dewey in 1971 and based on the assumption that for a set of closely grouped foci the combined station and path correction for each station is a constant. To cut a long story short, the use of this technique has enabled relative locations of foci to be determined with a precision of less than 5 km.

With this accuracy, Billington and Isacks show that in two separate cases the earthquakes within a deep cluster lie along, or parellel to and very close to, one of the nodal planes of a large-magnitude event within the cluster. They therefore suggest that these two planes are, in fact, fault planes and that there are probably other such planes corresponding to other clusters. Be that as it may, the two observed planes are nearly vertical and have linear dimensions of about 40 km, which means that the vertical dimension of the lithospheric slab in this particular deep section of the Tonga Arc must also also be at least 40 km (corresponding to a lithospheric thickness of at least 35 km). For the time being, however, the way in which supposed faults relate to the tectonics of the subducting lithospheric slab remains completely unknown.

The past as the key to the present

from D. H. Tarling

DURING the last month 69 papers and a similar number of discussion contributions have been presented at two meetings concerned with the early history of the Earth and Proterozoic tectonics Many significant and often apparently contradictory views were expressed about this period that covers the first 4,000 million years of the Earth's existence.

One of the main items of agreement seems to have come from the dating of lunar rocks and fly-by studies of the terrestrial planets, as it was generally agreed that the Earth experienced a very rapid segregation of its core during a near-molten phase within some 50–100 Myr of its accretion. There was also general but not unanimous agreement that the cessation of major planetesimal infall some 3,900 million years ago means that only localised tectonic features are like to have resulted from impact phenomena so that the apparent similarity between the lunar mare basalts, all younger than 3,100 Myr, and the terrestrial Archaean greenstone belts, some 2,700 Myr old, is fortuitous.

But points of significant dispute immediately arose even from consideration of the accretion process. If the accretion was of an essentially homogeneous mixture, then the earliest core–mantle–crust composition would be geochemically controlled, but inhomogeneous accretion, with predominantly iron-rich material at first, followed by more chrondritic materials, could mean that the composition of the upper mantle was modified after the primary segregation had taken place. From there on the story gets even more interwoven with the inevitable problems of isolating geological facts from interpretations, sorting out semantic problems such as what is understood by plate tectonic processes, and the lack of understanding between different specialisations even when tackling similar problems. These are, of course, the main reasons for meetings such as the very successful NATO Advanced Study Institute at Leicester (April 5–11) and the discussion meeting at the Royal Society (March 13 and 14).

One of the most critical papers for understanding Archaean tectonic processes (before 2,500 million years) was by S. Moorbath (University of Oxford) who demonstrated, in his usual thorough manner, that a very large proportion of strontium and lead isotopes in both granite and volcanic rocks of this age could not have originated by the reworking or partial melting of significantly older sialic crust but must have been derived from the upper mantle. Thus Archaean greenstones and granitic gneisses must have been derived by at least a two-stage process from mantle sources and the metamorphism of the gneisses must have occurred during their emplacement or certainly not more than 50–100 million years later. This evidence will take some time to evaluate, but it clearly means that the Archaean crusts must have been at least comparable in thickness to the present continental crust and that some tectonic process similar to modern plate tectonics probably existed at this time.

The possibility of applying plate tectonic models during this early period was mentioned by several speakers, some for and some against, but the inevitably higher heat flow due to radiogenic heat production must have strongly enhanced convective motions at this time and the higher thermal gradiants would also mean that subduction zones, although more active, would be shallow, possibly accounting for the absence, compared with Phanerozoic times, of andesites (other than those that now seem to be mechanical mixtures of basalts and andacites rather than geochemical differentiates). Nonetheless, there are many features that seem difficult to reconcile with current plate tectonic models; for instance the greenstone belts comprise some 7–10 km of volcanics, usually with interbedded sediments and divded in some areas into two distinct suites. Such belts, each originally covering some 1,500 km,

Elusive hepatitis A virus identified

from Arie J Zuckerman

THE discovery of a specific antigen associated with hepatitis B virus infection has heralded an era of unprecedented progress in our knowledge of this type of infection and in the pathogenesis of liver disease in general. Recent advances with epidemic hepatitis (*Nature*, **252**, 193; 1974), now referred to as hepatitis A, indicate that there may soon be an answer to this hitherto insoluble problem.

The pioneering work of Deinhardt and his colleagues on the transmission of human hepatitis A to species of marmosets (*J. exp. Med.*, **125**, 673; 1967 and *Nature*, **243**, 419; 1973) were confirmed by painstaking experiments conducted over a period of five years by Mascoli *et al.* (*Proc. Soc. exp. Biol. Med.*, **142**, 276; 1973). An agent designated as CR 326 was isolated in Costa Rica from the serum of a child with classical hepatitis A. This virus was passaged serially in marmosets and it was concluded that certain species of marmosets, particularly *Saguinus mystax*, are highly reliable for detecting and propagating human hepatitis A virus. This work was extended by Provost *et al.* (*Proc. Soc. exp. Biol. Med.*, **142**, 1257; 1973) who found that all patients with hepatitis A infection developed antibody which neutralised the CR 326 enterovirus-like agent, but there was no such antibody response in patients with hepatitis B.

In the same year, Feinstone and colleagues (*Science*, **182**, 1026; 1973) demonstrated by immune electron microscopy virus-like particles measuring 27 nm in diameter in faecal extracts obtained from two out of four adult volunteers who were infected with the MS-1 strain of hepatitis A virus (see also *Nature*, **252**, 193; 1974). Similar observations have now been reported on natural hepatitis A by other groups from Australia (Locarnini *et al.*, *Intervirology*, **4**, 110; 1974) and from Arizona (Gravelle *et al.*, *J. infect. Dis.*, **131**, 167; 1975). But perhaps the most exciting reports have emanated from the laboratories of Hilleman and colleagues who developed specific serological tests for hepatitis A antibody using the CR 326 virus antigen. Hilleman presented data at symposia held recently in Milan and in Washington on complement fixation and immune adherence tests. Patients with hepatitis A developed complement fixing and immune adherence antibody soon after the onset of the acute illness and the antibody persisted thereafter. Limited seropidemiological studies have shown that most individuals of a low socio-economic level had hepatitis antibodies and these antibodies were detectable for at least seven years after infection. In contrast, most persons of high socio-economic status in an area of low hepatitis A incidence may proceed to adulthood without infection with hepatitis A.

The availability of serological tests for hepatitis A will provide a valuable tool for diagnosis, for epidemiological studies for detection of hepatitis A virus in attempts to propagate the virus in cell cultures, for the identification of susceptible and immune persons, for assay of hepatitis A antibody in batches of human immunoglobulin and ultimately for vaccine development. A new era in hepatitis research has just begun.

could be entire marginal basins obducted on to the existing crust or, if not stratigraphically continuous, they could represent a series of such basins. On the other hand, if they are taken as Archaean oceanic basins, then they must have since been 'underplated' by sialic rocks to place them in their present setting, as the greenstones are obviously cut and distorted by the diapirically rising later granites, and there is a further 30–40 km of continental crust below the greenstones. Bearing these models in mind, more field work is required, particularly to look for the major shortening and thickening of the crust evidenced by the existence of major nappes and thrusts, now identified by M. Coward (University of Leeds) in Botswana and Rhodesia, before the imposition of intense deformation and migmatisation.

At the start of the Proterozoic, about 2,500 million years ago, or possibly within it (roughly 1,800 million years ago) there seems to have been a marked vertical stabilisation of the existing continental crust. From those times, J. V. Watson (Imperial College, London) showed that it becomes easier to identify the different major continental blocks at almost their present elevation, and the old-established Archaean lineations remained as major factors in controlling the location of Phanerozoic continental separations and possibly mineralisation belts. Evidence for the persistence of horizontal crustal movements during these times was provided by palaeomagnetic studies, although, as E. Irving (Department of Energy, Mines and Resources, Ottawa) pointed out, more than 80% of the available data are still from North America. Revision of even these good North American data illustrated how the palaeomagnetic story from the Precambrian is only at a similar stage to that for the Phanerozoic some 20 years ago.

The possibility of obtaining palaeomagnetic data from the ancient Isua ironstones and Ameralik dykes of South-west Greenland, mentioned by W. Fahrig (Geological Survey of Canada), could provide major evidence on the nature of the Earth's core, 3,760 Myr ago and thus provide stringent constraints for the later evolution of the Earth's mantle, for which G. N. Hanson (State University of New York, Stony Brook) briefly presented apparently convincing geochemical data (to appear shortly in *Geology*), not only for the present existence of deep mantle plumes, but also for a gradual change from an initial mantle-wide major circulation system to the present convection within the asthenosphere.

The Isu formation also figured in consideration of the origin of life on this planet as spheroids within it, some 5–30 μm, could indicate the existence of living matter at this time. More reliable evidence of life, stromatolites, were described within the Rhodesian greenstone belt, some 2,800 Myr old, and the argument about the biogenic nature of structures within the 3,375 Myr Onverwacht Group of South Africa continued. It is, however, in South-west Greenland that the oldest rocks in the world are best exposed and field mapping of the Isua area is likely to be completed next year. There seems to be an excellent case for a 'lunar' type project in this area, bringing to bear all the biological, geological, geochemical and geophysical tools available in order to evaluate the nature of the Earth as soon after its inception as possible.

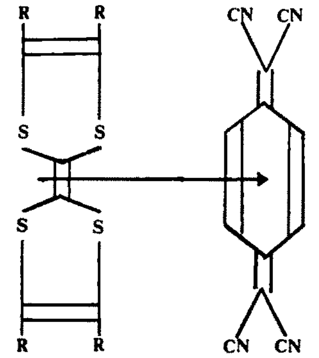
Electronic structure of organic semiconductors

from Andrew Holmes-Siedle

THE cost of semiconductor devices is quite high because, in order to prepare inorganic semiconductors such as silicon or gallium arsenide of the required quality, single crystals must be grown at high temperatures. One of the hopes of manufacturers is that some new material will be developed which can be converted more easily from raw material to finished electronic devices, if possible using a flow process rather than the highly specialised batch processes used at present.

One large range of materials which holds out hope is that of the organic semiconductors. In spite of the normally very poor conductivity of common organic molecules, the fact that organic materials melt, sublime or evaporate at low temperatures and that the raw materials are very cheap have kept physicists working to understand, control and enhance the conductivity of organic media Our good knowledge of the electronic structure of large organic molecules with conjugated double bonds reinforces the hope that the strong local mobility of electrons found within the π orbitals of these systems can in some way be extended over many molecules to endow an organic medium with bulk conductivity.

Progress towards a usable organic semiconductor has been slow over the past ten years (nobody, for example, has yet found a controllable method for forming p–n junctions in organic media). But some interesting prospects remain. One class of materials, the aromatic charge-transfer complexes, such as the complex shown in the figure, while not possessing band conductivity, exhibits very high conductivity (sometimes in the metallic range but more often in the semiconductor range). This occurs by some kind of very efficient hopping process along stacks of the acceptor molecule which have extended wave functions, leading to weak overlap with a neighbour in the stack. Theoretical calculation indicates that several occupied electronic states existing in the tetracyanoquinodimethane molecule are raised considerably in energy by the donation of electrons to this molecule in the charge-transfer complex and that these electrons are the ones which can be transported over large distances (Berlinsky, Carolan and Weiler, *Solid State Commun.*, **15**, 795; 1974).



Tetrathiofulvalene (TTF) **Tetracyano-p-quinodimethane (TCNQ)**

R=H: conductivity 350 $(\Omega\,\mathrm{cm})^{-1}$ (metallic); R=alkyl: conductivity variable but usually semiconducting.

An elegant confirmation of the effect of electron donation on electronic states in TCNQ has recently been demonstrated by Schechtman, Lin and Spicer (*Phys. Rev. Lett.*, **34**, 677; 1975). Previous work had shown that complex formation produced a major effect on the ultraviolet photoelectron spectra (UPS) of TCNQ when alkali metals were reacted with this molecule. The simplicity of the metal ion as donor made the observations less ambiguous than for organic donors. However, since the source of the photoelectron emission is a very thin surface layer, uncontrolled surface impurities could still confuse the result. The new work reduces that possibility by reacting caesium vapour at very low pressure with a freshly sublimed TCNQ film while UPS measurements are made continuously. Before 'caesiation', the TCNQ emission peak is observed at an energy which corresponds to an occupied electronic state at 3.5 eV below the Fermi level. As the caesium vapour reacts, this peak is reduced while two new peaks grow at levels 2.1 and 1.0 eV below the Fermi level. The authors' interpretation is that the 2.1 eV peak is a new position for the state, of symmetry $3b_{1u}$, which was originally at 3.5 eV. They suggest that the 1 eV state is a new 'affinity level', associated with complex formation. These interpretations couple well with the hypothesis of ordered stacks described earlier which, in turn, requires that occupied states must lie very near to the Fermi level so that hopping is frequent.

Interest in the TCNQ series has increased since it was reported (Engler and Patel, *J. Am. chem. Soc.*, **96**, 7376; 1974) that by replacing some S atoms by Se in tetrathiofulvalene, the conductivity of the system can be manipulated conveniently. As far as techniques go, dynamic methods such as the *in situ* UPS method of Spicer's group seem to have the required level of accuracy and directness to throw light on intermolecular bonding in organic compounds. What now remains to be seen is whether intermolecular electron transport parameters can be shown to change dynamically in concert with these measured properties of the individual molecule.

Multi-subunit proteins at Bristol

from John C. Wootton

In a brave attempt to foster communication between crystallographers, biochemists and geneticists working on subunit interactions in proteins, the British Biophysical Society joined with the Molecular Enzymology Group of the Biochemical Society to organise a meeting on 'Multi-subunit Proteins—Structure, Assembly and Control' held at the University of Bristol, March 25–27, 1975.

To what extent do intersubunit interactions stabilise the conformation of individual subunits? Solution studies of the reversible dissociation and deactivation of lactate dehydrogenase, glyceraldehyde-3-phosphate dehydrogenase and aldolase were reported by R. Jaenicke (University of Regensberg). Whereas in lactate dehydrogenase inactivating structural changes always seemed to accompany or precede dissociation of the tetramer, various lines of evidence pointed to the occurrence of active isolated subunits of the other two enzymes. All three enzymes will reassociate to the native active tetramer in good yield under conditions which minimise the formation of higher aggregates of incorrectly folded subunits. There was stimulating but inconclusive discussion of how such solution measurements, considered together with intersubunit hybridisation studies, could be interpreted in terms of the number and type of intersubunit bonds known from crystallographic structures. The wealth of high resolution structural information pertaining to subunit interactions and conformational changes in alcohol, malate, lactate and glyceraldehyde-3-phosphate dehydrogenases was reviewed in talks by C.-I. Branden (Agricultural College, Uppsala) and M. G. Rossman (Purdue University).

Direct attacks on the kinetics of subunit assembly and the associated conformational changes were described by K. Kirschner (University of Basel) on the *Escherichia coli* tryptophan synthetase $\alpha_2\beta_2$ tetramer, and by H. Schachman (Berkeley, California), on *E. coli* aspartate transcarbamylase. A pleasing feature of tryptophan synthetase is that activity of isolated α subunits and β_2 dimers can be assayed separately as partial reactions. Assembly to $\alpha_2\beta_2$ is accompanied by conformational changes and increases in substrate affinity and catalytic efficiency. Impressive experimental ingenuity features in both these studies.

Multi-enzyme complexes are well adapted for catalytic efficiency and substrate channelling in situations where free pools of intermediate substrates are undesirable because of instability or interference with other pathways. Multifunctional polypeptides provide a neat means of ensuring a one-to-one ratio of different catalytic activities, and form the basis of a new model for the yeast fatty acid synthetase complex proposed by E. Schweizer (University of Wurzburg). Elegant genetic and biochemical studies of temperature-sensitive fatty acid auxotrophs revealed only two structural genes (which are unlinked (specifying the complex: *fas-1* encoding the dehydration, second reduction, acetyl and malonyl transfer activities, and *fas-2* encoding the condensation, first reduction, and acyl carrier activities. Purified complex dissociated into only two polypeptide chains of molecular weights approximately 185,000 and 175,000. In Schweizer's model the whole complex is built of six repeats of the two-chain, seven-activity structural subunit. This contrasts with Lynen's earlier model in which each structural subunit was assumed to carry a different single activity Interesting genetic criteria were developed which distinguish a multifunctional gene from a gene cluster or an operon· pleiotropic nonsense and frameshift mutants are scattered throughout the fine-structure genetic map, as are pleiotropic, noncomplementing mis-sense mutants (interpreted as defective in folding or assembly of the complex). Evolution of these multifunctional chains from the prokaryotic type of synthetase presumably involved gene fusion.

In the case of the pyruvate and 2-oxoglutarate dehydrogenase complexes of *E. coli* the stoichiometry of the three-component polypeptides is still undecided. R. N. Perham (University of Cambridge) described chemical modification and reconstitution experiments in which a ratio approaching 2 : 1 : 1 of E_1 (decarboxylase): E_2 (lipoyl transacylase): E_3 (lipoamide dehydrogenase) was obtained in the best preparations. But deficiencies of E_1 and E_3 were often observed, and variation in these may account for discrepancies between different laboratories. Perham favours a model based on a 24-subunit 'core' of E_2 with 432 octahedral symmetry, on the surface of which are binding sites (which may be partially unoccupied) for 24 dimers of E_1 and 12 dimers of E_3. Unlike E_1 and E_2, the lipoamide dehydrogenase component is apparently common to and interchangeable between the pyruvate and 2-oxoglutarate dehydrogenase complexes. This is a flavoprotein containing a disulphide bridge which is alternately oxidised and reduced in the catalysis and forms an intrachain six-residue loop. The sequence around this loop is almost identical in the enzymes from *E. coli* and pig heart lipoamide dehydrogenase, and also in yeast glutathione reductase (see Table). It may be a common structural feature of some flavoprotein dehydrogenases, but the four-residue disulphide loop of *E. coli* thioredoxin reductase is not homologous.

Both G. K. Radda (University of Oxford), on the glycogen phosphorylase system, and P. J. Randle (University of Bristol), on the regulatory role of phosphorylation of the mammalian pyruvate dehydrogenase complex, attempted to relate the properties of the purified enzymes to control *in vivo*. Radda described how ^{31}P NMR spectroscopy could be used to estimate the concentrations of free and protein-bound ligands in whole glycogen granules and, in preliminary experiments, in intact rat muscle. Differences between phosphorylase control in the granules and *in vitro* can be explained as resulting from protein-bound metabolites. Solution studies of phosphorylase using spectroscopic probes revealed a multiplicity of ligand-specific conformational changes These are interpreted as locally differing varia-

tions on only two kinetically significant states. Perhaps many regulatory enzymes, including some of bewildering conformational multiplicity, will prove to be systems of essentially two or a few states.

Naturalists of the past

from a Correspondent

The Society for the Bibliography of Natural History held an Easter Meeting at the Linnean Society on April 3 and 4.

SINCE natural history is a descriptive science firmly rooted in history the researcher in the field has often to consult the older literature and unpublished manuscripts. The four sessions into which the meeting was divided reflected some of the diverse interests of natural history: manuscripts, exploration, descriptive bibliography and social history.

Roy Porter of Churchill College, Cambridge, considered William Hobbs's unpublished *The Earth Generated and Anatomized*, a recent acquisition of the British Museum (Natural History). Practically all that is known about Hobbs is that at one stage of his life, in the late seventeenth or early eighteenth century, he was a government official employed at Weymouth harbour. Although he seems never to have published anything he certainly exchanged ideas with other men of science about the theory of the Earth Opposed to the Woodwardian school that the flood was an agency of fossil distribution, his theories gave a greater prominence to the role of tides in the creation of the Earth. Mr Porter will publish this manuscript after which some reassessment of late seventeenth and early eighteenth century theories of the Earth will be necessary.

The most important purchase made by the Natural History Museum in recent years is the large collection of Sowerby papers. Various members of this talented family played a significant part in the development of British natural history and engraving during the eighteenth and nineteenth centuries by writing or illustrating over one hundred books on botany, zoology, mineralogy and palaeontology. R. J. Cleevely of the Natural History Museum gave a résumé of the material which is as yet an untapped source of information on the production of scientific books in the last century. The Backhouses of Darlington and York, well-known as bankers and nurserymen, were also seminal figures in the growth of natural history studies in the north of England during the eighteenth and nineteenth centuries Colin Simms of the York Museum where the Backhouse collections of plants, bones and bird skins are housed reviewed their work as naturalists. J. Pingree discussed manuscripts at Imperial College, including the papers of T. H. Huxley and Sir A. C. Ramsay.

Michael Hoare of the Australian Academy of Science argued for a more important status in the history of science and letters for Johann Reinhold Forster (1729–98), the controversial naturalist of Captain James Cook's second voyage (1772–75). Phyllis Edwards of the Natural History Museum talked about the botanist, Robert Brown, and the collections of plants, animals and minerals he made during Matthew Flinders's voyage to Australia (1801–05). Peter Whitehead, also of the Natural History Museum, described Piso and Marcgrave's *Historia naturalis Brasiliae* (1648), an important early work on the botany, zoology, medicine and ethnology of Brazil. He is still pursuing his search for the missing original drawings on which the woodcuts in this work were based. Natural history has its share of megalomaniacs and frustrated scientists. G. C. Wallich, naturalist on HMS Bulldog in 1860, became embittered through his vain endeavours to achieve recognition for his scientific work. Antony Rice of the Institute of Oceanographic Sciences in a paper written in conjunction with Dr Burstyn and Dr A. Jones recalled some of the scientific controversies in which Wallich got involved.

When the same plant or animal has been discovered and named independently by different naturalists it is necessary to determine who named it first. Descriptive bibliography, that is the study of books as physical objects, is a discipline frequently called upon to resolve such taxonomic problems by determining dates of publication. John Thackray of the Geological Museum opened the third session with an examination of James Parkinson's *Organic Remains of a Former World* (1804–11) and its various editions and issues. George Washington Sleeper's *Shall we have Common Sense* was found among his papers after his death in 1903. It bore the date 1849 and seemed to anticipate Darwinian theories. A R. Wallace, convinced of its authenticity, communicated it to the Linnean Society and Professor E. B. Poulton made it the subject of his presidential addresses to the Linnean Society in 1913 and 1914. John Collins of Sotheby and Company demonstrated how the application of bibliographical methods proved conclusively that this pamphlet was a forgery. Since illustrations are an integral part of many natural history books it is rather surprising that their biolographical description still remains imprecise. Gavin Bridson, the Linnean Society's Librarian, maintained that a greater knowledge of graphic reproduction processes is required before principles can be formulated for a more exact description of plates in books. Mr Michael Walpole examined textual and plate variations in the editions of William Curtis's *Flora Londinensis*.

David Allen of the Science Research Council traced a pattern of social development in British natural history over the past three hundred years, showing the interaction of natural history and social history. Phillip Lowe of University College, London complemented Mr Allen's thesis with a review of the relationship between amateurs and professionals in the development of science, taking as a case history the emergence of ecology as a scientific discipline. M. McNeil of Darwin College, Cambridge concluded the session with a critique of Erasmus Darwin, who formed a link between natural history, medicine and literature.

The rise of palaeobiology

from A. Hallam

MOST geologists still regard palaeontology as the handmaiden of stratigraphy. That fossils are invaluable in the establishment of a relative time scale was recognised by early last century, and concerns as practical in their objectives as oil companies have felt the need to employ a variety of micropalaeontologists to correlate their boreholes. There is more, however, to stratigraphy than correlation and dating. In its broader sense it is concerned with the interpretation of ancient environments and here again fossils are of great utility. A fossil reef coral, for instance, can tell us much about the ambient sea water temperature, salinity and depth.

The term palaeoecology has been widely used to embrace a variety of disciplines aimed at learning more about environments in the past, such as analysis of the processes affecting fossilisable organisms between death and burial, or the application of knowledge of the tolerances of living organisms to their fossil relatives. The goal in both cases is a geological one and in no proper sense could this sort of work be considered to contribute to our further understanding of biology.

If one attends palaeontology courses in the geology departments of most universities one might be forgiven for failing to appreciate the third great value of fossils. They are the only direct evidence we have of the history of life, of the patterns and rates of large-scale evolution. Palaeontology can in fact provide the invaluable time dimension missing from the subject matter of evolutionary geneticists and ecologists. We might even learn something, furthermore, not just about phyletic lineages but about the evolution of certain communities or ecosystems. Partly as a reaction to what they regard as the somewhat arid scholasticism of a subject devoted more to classification than problem solving, but more positively because they have become excited by new biological concepts and wish to apply them to fossils, a number of younger researchers would now prefer to call themselves palaeobiologists.

The term was used explicitly three years ago in a well-received book edited by T. J. M. Schopf and entitled *Models in Paleobiology*, in which a number of authors devoted themselves to setting up and testing models at a variety of levels ranging from individual growth to ecosystems. Schopf is now the joint editor, with his Chicago colleague R. G. Johnson, of a new journal called *Paleobiology*, published by the American Paleontological Society—the first number appeared in March this year. The editors hope to publish original contributions dealing with any aspect of biological palaeontology, including morphology, biogeochemistry, populations, faunal provinces, communities and ecosystems. The emphasis is on biological processes and patterns including speciation, extinction, development of individuals and colonies, natural selection, evolution and patterns of variation, abundance and distribution in space and time.

How does the first number of the journal measure up to this ambitious programme? Five of the articles are concerned with aspects of functional morphology. Gould and Katz give a computer simulation of the spirally arranged facets of a Silurian receptaculitid and discuss the significance of the geometrical insights thereby obtained. Hopson argues persuasively that the prominent cranial crests of hadrosaurian dinosaurs were sexual display structures and Stanley describes experiments undertaken to throw light on what controls the shape of burrowing bivalves. Two other short articles are concerned with the musculature of brachiopods and crinoids.

The remaining four articles deal with more general matters. Schopf, Raup, Gould and Simberloff continue their computer simulation of phylogeny and argue that fossils of more complex morphology may only appear to have evolved more rapidly, and more controversially that rate of morphological change might bear little or no relation to the underlying genomic evolution. With reference to the evolutionary history of the arthropods, Flessa, Powers and Cisne challenge the widely held assumption that generalised organisms have persisted longer than specialised ones. Raup writes a methodological essay on taxonomic survivorship curves and Levinton and Bambach compare a Silurian with a modern bivalve community. The quality of the papers, in terms of data, thought and presentation, is almost uniformly high.

All the authors of the first issue of *Paleobiology* and the whole editorial board are American. This reflects the fact that the revitalisation of an old discipline has taken place almost entirely in America, probably chiefly because of the flexible teaching system which will allow a student interested in fossils to take biology courses and equip himself for this new area of research.

Are X-ray stars and pulsars related?

by John Gribbin

THE juxtaposition of two papers in *Nature* last week emphasises just how close astronomers may be to producing a unified model of two of the most intriguing discoveries of recent years: X-ray stars and pulsars. According to Tademaru and Harrison (**254**, 676; 1975) pulsars may be accelerated to high velocities by asymmetric emission of low frequency electromagnetic radiation. This is a welcome suggestion for the theorists, since although the theories require that pulsars are formed in supernova explosions, and supernovae are thought only to occur in binary systems, only one pulsar out of more than 100 discovered is known to be in a binary system Clearly, for the theories to hold up the pulsars must have some means of escape from the binaries in which they are born, and the Tademaru–Harrison hypothesis is one intriguing possibility.

Clark, Parkinson and Caswell, on the other hand, have been studying Cir X-1, an X-ray source which may well be both a binary and a remnant left over from a supernova explosion (**254**, 674; 1975). They suggest that Cir X-1 is a runaway from the supernova remnant G321−0.3, and that the X-ray source is in a highly elliptical orbit around a companion. Most models of X-ray stars require the presence of a companion, from which matter falls on to the X-ray star itself to produce X-rays by conversion of gravitational energy into radiation. So it seems plausible that they may be produced in supernova explosions which have not unbound the parent binary system.

Cir X-1, however, is almost an intermediate case. If the model of Clark *et al.* is correct, then the ellipticity of the system now seen is so great that the mass transfer, X-ray mechanism switches off for a time around apastron, when the two components are furthest apart, thus mimicking an eclipse. It is very tempting to see an overall pattern emerging from the observations of X-ray stars and pulsars, in which some systems remain tightly bound after the supernova event, producing 'standard' X-ray sources, others become runaway pairs in which the system remains bound but highly elliptical, producing unusual X-ray stars such as Cir X-1, and in still others the neutron star escapes completely, running away on its own to be seen as a pulsar.

There is one further, interesting implication of these ideas, and that concerns the nature of the star left behind when a pulsar does run away from such a binary system. As the companion must have been involved in mass exchange during the lifetime of the binary system, it may well seem to be highly evolved for its mass; in addition, of course, it is likely to have been somewhat disturbed by the supernova event itself. One consequence of the Tademaru–Harrison model, however, is that there is no need to suggest that if the pulsar accelerates away from the sight of the explosion in one direction then the companion must have moved away in the opposite direction, as there would be an energy mechanism for moving the pulsar independently of its erstwhile companion. So a search for odd, highly evolved stars near the centres of known supernova remnants might not prove entirely fruitless, even if there is already good reason to associate a known runaway pulsar with the particular supernova in question.

A hundred years ago

ON LIGHTNING FIGURES

THE letter headed "Struck by Lightning", and signed "D. Pidgeon", contained in NATURE, vol. xi. p. 405, is valuable, and the more so because it is unaccompanied by any theory. Formerly, when ramified marks appeared on the persons of men or animals, they were always referred to some near or distant tree, of which the marks formed "an exact portrait." Thus, in the *Times* of September 10, 1866, is an account of a boy who had taken refuge under a tree during a thunderstorm, having been struck by lightning, and on his body was found "a perfect image of the tree, the fibres, leaves, and branches being represented with photographic accuracy."

From *Nature*, **12**, 9, May 6, 1875

The GARP Atlantic tropical experiment

B. J. Mason*

The Atlantic Tropical Experiment (GATE), the first major observational experiment of the Global Atmospheric Research Programme (GARP) and designed to explore the tropical atmosphere, was successfully completed in September 1974. In what was probably the largest and most complex international scientific experiment ever undertaken, ten nations—Brazil, Canada, France, Federal Republic of Germany, German Democratic Republic, Mexico, Netherlands, USA, UK and USSR—working in close collaboration, contributed 39 specially equipped ships, 13 large research aircraft, several meteorological satellites and some 5,000 personnel to an intensive three-month study of weather systems in the tropical eastern Atlantic Ocean; in addition, some 50 countries in Africa and South America participated by making additional surface and upper-air observations.

METEOROLOGICAL disturbances in the tropics, which behave differently in many respects from those in middle latitudes, play an important role in the circulation and energetics of the atmosphere as a whole. A better understanding of their working is essential not only for the improvement of weather forecasting in the tropics but, unless their influence is taken into account, it may not be possible to predict the weather in middle latitudes for more than a few days ahead. The main task of the GATE project was to study the structure and evolution of these disturbances and to assess the efficacy of cumulus convection in transporting heat and moisture from the tropical oceans into the global circulation.

Study of large scale tropical disturbances

Most tropical rainfall is produced by convective systems which are the principal mechanisms for vertical transport of heat and water vapour, and probably of momentum. Satellite observations show that tropical convective clouds are not randomly distributed but tend to form in large organised clusters 100–1,000 km across. These clusters are associated with the development of large-scale disturbances, such as the intertropical convergence zone (ITCZ), in the equatorial wind field, and with the troughs of the easterly tropospheric waves which originate often over Africa and sometimes over the Indian Ocean, to proceed across the Atlantic. At least three distinct families of tropical wave disturbances have been identified; the easterly waves of wavelength 2,000–4,000 km in the troposphere, mixed Rossby-gravity waves of 8,000–10,000 km wavelength in the lower stratosphere, and a Kelvin wave of planetary scale in the stratosphere. One of the tasks of GATE is to establish the characteristics of these waves over the tropical Atlantic and the African and South American continents in the belt between 10 °S and 20 °N, to determine their origin, structure, development, propagation, their energy sources, momentum and heat transfers, and relate these to the behaviour of the cloud clusters.

The basic observations of the temperature and wind fields on this large 'A' scale were provided by enhanced synoptic upper-air networks over Africa and South America, supplemented by soundings from GATE ships in the Atlantic and by winds obtained from cloud movements as observed from a geostationary satellite. The network of radio-sonde and radio wind-finding land stations and of some 15 dedicated A-scale ships is shown in Fig. 1. The Russian ships used a radar wind-finding technique whereas most of the remainder used a new balloon-borne transceiver the position and movements in space of which were determined by measuring the time differences between signals received from a number of fixed ground stations belonging to the OMEGA and VLF navigational systems, the computations being performed by small computers on board the launching ships.

Cloud clusters

A much finer network of observations was required to resolve the internal structure of the cloud clusters and the effects of these clusters on the circulation in their immediate environment including the production of compensating downdraughts, the momentum, heat and moisture fluxes into and out of the system at various levels, and the total release of latent heat. Satellite images of the clouds with the contrast enhanced to delineate active convective areas, show that the clusters are composed of meso-scale convective units of up to 100 km in diameter which, in turn, contain a number of cumulonimbus cells of 1–10 km diameter. A much more detailed picture is required, however, to produce a useful working model.

Accordingly there was established a special meso or 'B'-scale network of some 15 observing ships in a 800 × 800 km polygon some 1,000 km off the coast of Africa, south-west of Dakar, in a region where satellite photographs led us to expect a high frequency of cloud clusters, perhaps 10–20 during the 3-month period of the experiment. These ships were required to determine winds to an accuracy of ± 1–2 m s^{-1} averaged over vertical depths of 1 km. Several were equipped with C or X-band radar to explore the internal structure of the cloud clusters and obtain quantitative estimates of the precipitation intensity in order to evaluate the release of latent heat.

A full understanding of the behaviour and effects of cloud clusters will not be achieved without consideration of the fluxes of these quantities produced by the meso-scale convective systems on the 10 km C-scale, and even by individual cumulus cells and smaller-scale motions on the 1 km D-scale. Although these could not be measured throughout the volume of a cloud cluster, sample measurements by specially instrumented aircraft of the motion field of the systems, their spectra of turbulence,

---

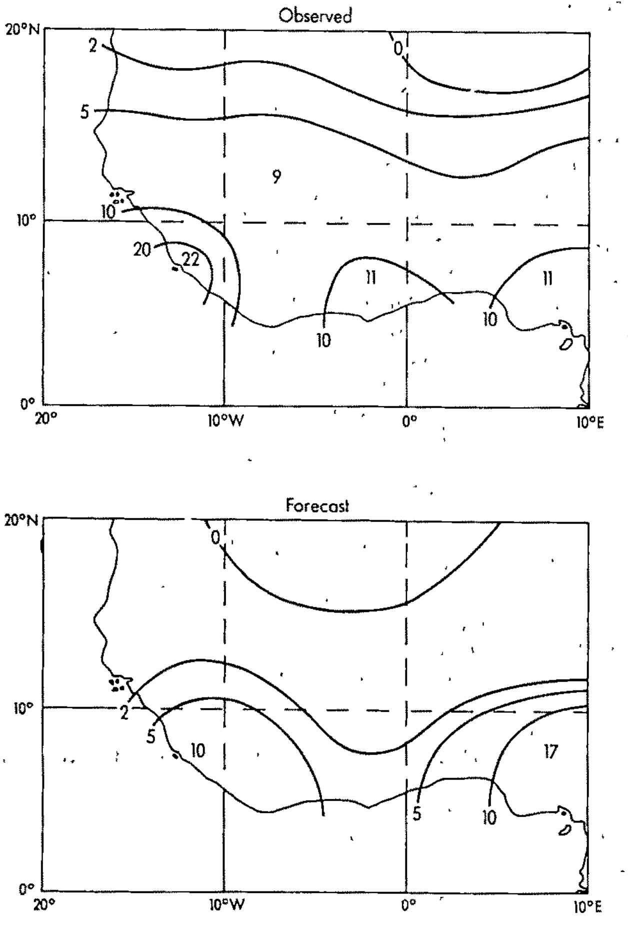
temperature, liquid-water content and precipitation intensity should provide a valuable indication of their distribution and significance.

Interaction of cloud clusters and larger-scale disturbances

Recent analyses of satellite pictures have revealed that the axes of cloud clusters often coincide with the trough lines of tropical waves and that the fields of divergence, relative vorticity and vertical velocity of persistent clusters coincide quite well with similar fields of the easterly waves. This suggests a close relationship between these systems, with the clusters acting as the rain areas of the wave disturbances. Yet the life times of the clusters (at most a few days and sometimes only several hours) are much shorter than those of the waves (1–3 weeks). Other cloud clusters form in the ITCZ but again their relationships and interactions are obscure and provide an important task for GATE.

Fig. 2 Mean 24-h rainfall (mm) for the period September 4–14 1974 as forecast by the Meteorological Office numerical tropical model compared with the corresponding observed rainfall amounts.



Meanwhile, it has been suggested that convergence in the trade-wind boundary layer produces vertical motions at the top of the layer which, in turn, induce the release of latent heat as a result of the existing conditional instability. The resulting circulation is amplified as the vorticity increases at a rate determined by the linear dimensions of the circulation, the Coriolis parameter and the lapse rate of equivalent potential temperature, and leads at some optimum distance from the equator to the formation of a narrow band of convection—which may be identified with the ITCZ. Alternatively, one may think in terms of the belt of high sea-surface temperature located several degrees from the equator promoting convective activity at these latitudes which, in turn, could excite the development of waves of frequency appropriate to the Coriolis parameter at that latitude. This seems a reasonable explanation for the production of the easterly waves which may then interact with the ITCZ and partially account for its observed variability.

Energy-exchange processes

Whatever the detailed dynamics of these disturbances, which must involve interactions between motions of different scales, their primary role is to link the tropical oceanic heat sources to the global circulation through a series of processes of energy exchange that can be summarised as follows. The absorption and storage of solar energy in the upper layers of the tropical oceans and its transfer to the overlying atmosphere, mainly by turbulent fluxes of water vapour evaporated from the sea surface; continued upward transport of energy through the atmospheric boundary layer by cumulus convection; the release of the accumulated latent heat by condensation in deep-meso-scale convective systems and its distribution to higher levels and over wider areas in precipitating cloud clusters; poleward transport of the heat released in the clusters by the mean meridional Hadley circulation, upper tropospheric waves and standing eddies to feed the global circulation.

These considerations indicated the need to determine the convergence of air in the boundary layer between sea surface and cloud base and to measure the associated fluxes of heat, moisture and momentum, both near the surface and up to cloud base. In disturbed weather, with enhanced cloudy convection, cloud induced mixing may extend below cloud base and couple sea-surface processes with the overlying troposphere. Supporting research programmes to measure at various levels both mean and fluctuating components of the wind, temperature and humidity fields with the required accuracy provided a stringent test of the instrumentation under hostile conditions, a particular problem being with the interference with delicate sensors by radio transmissions from the ships and aircraft. Unique data have none the less been successfully collected on the boundary layer, both by aircraft and tethered balloons and by ships and buoys.

Since long term control of the structure of the tropical atmosphere and its propensity for developing convective disturbances is exerted by the radiative flux divergence, efforts were made in GATE to obtain vertical profiles of the solar and infrared radiative flux divergences and the upward and downward fluxes at both the ocean surface and the tropopause. Measurements at the Earth's surface were made from land and ship stations, but measurements at higher levels required the use of satellites, balloons and aircraft. Since the radiative fluxes were strongly affected by the cloud cover and the water-vapour content of the atmosphere, these quantities were determined independently, mainly from satellite measurements.

The oceanographic experiment

An international group of oceanographers working under the auspices of the ICSU Scientific Committee on Oceanic Research (SCOR) took advantage of the unprecedented concentration of ships assembled for GATE to carry out a parallel programme of observations to obtain independent estimates of the heat, moisture and momentum fluxes across the air–sea interface from measurements in the mixed upper layers of the ocean, and to investigate the response of the oceans to impressed atmospheric disturbances of various scales. Such information will be of great value in developing coupled ocean–atmosphere models for long range predictions of weather and climate.

On the A-scale, detailed studies were made of the structure and dynamics of the cold eastward Equatorial Undercurrent which may have considerable impact on the atmospheric circulation. Measurements showed it to oscillate about the Equator with a wavelength of about 2,500 km, a period of about 18 d and a westward phase speed of about 1.5 m s^{-1}. Measurements of currents, salinity and temperature by the B-scale array of ships will allow the corresponding transports and budgets to be computed. The response of the ocean to smaller scale disturbances such as cumulonimbus with their precipitation and cold downdraughts was followed through their influence on surface and internal waves, vertical current shear, fronts in the thermocline and the transport properties of the mixing layer. To this end, the RRS Discovery of the Institute of Oceanographic Sciences, the Canadian RS Quadra and the US Columbus Iselin towed specially designed probes to make fine-scale measurements of temperature and salinity in the upper 50 m of the ocean and to map horizontal features only a few kilometres across.

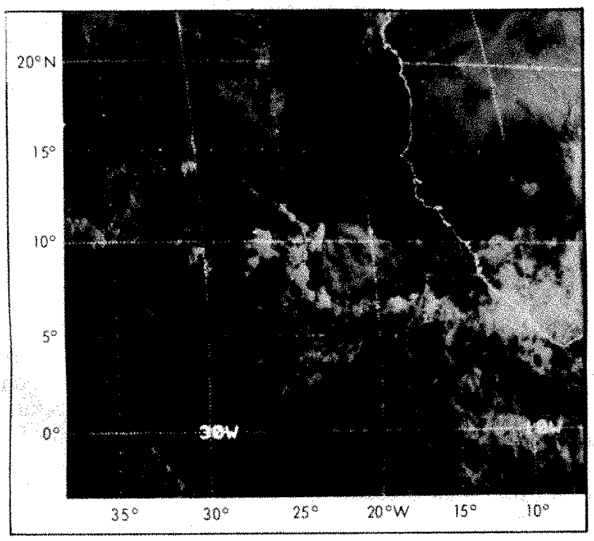

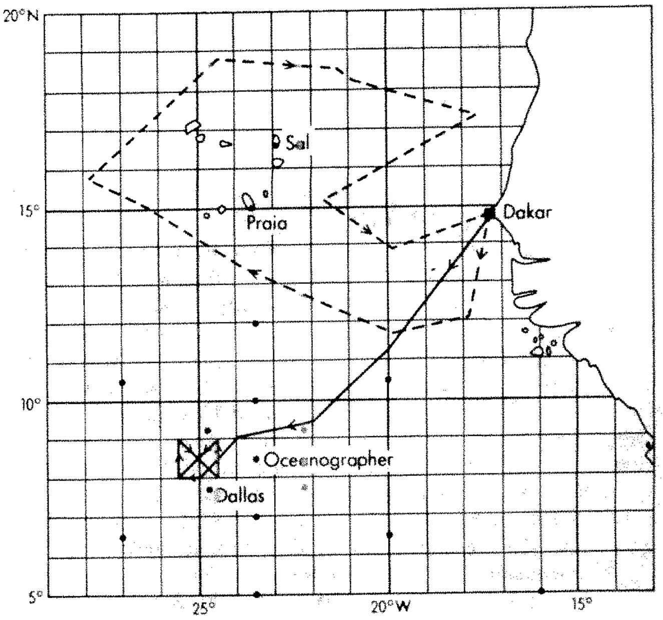

Fig. 4 The 'butterfly' flight pattern followed at several different levels by four research aircraft in exploring the cloud cluster on August 10, 1974 and the flight path (shown dashed) by the high level jet aircraft dropping sondes.

Numerical weather forecasts for the GATE area

During each observing phase of GATE, the Meteorological Office at Bracknell carried out a real-time forecast–analysis cycle updated every 12 h. In each cycle a forecast was produced by an 11-level numerical model developed very quickly for the GATE area and this produced a background field for observations made at the same time; the latter was used to modify the forecast fields and produce the analysis for the next forecast. In this way useful information can be propagated into areas of poor observation, and the best overall analyses obtained. The Meteorological Office experiment had three main objectives.

First, we wished to test new analysis techniques which were designed for the tropics. Most analyses carried out in middle latitudes make extensive use of the geostrophic relationship but in the tropics this is inappropriate. The new methods involved analysing the wind field independently of the pressure field and then adjusting them by a variational technique so that the accelerations implied were not excessive.

The second objective was to test the performance of a numerical forecasting model in the tropics. Numerical models have been shown to give good results in middle latitude conditions, where the main features are cyclones and anticyclones produced as a consequence of baroclinic instability. In the tropics the atmospheric features as large as typical cyclones are relatively weak while small features produced by convective instability are relatively much more important.

Finally, we hoped to carry out the experiment in near real-time to allow monitoring of the number and the quality of observations, to judge which periods should be considered of special interest for later intensive study and to give the personnel a sense of involvement in the GATE experiment as a whole.

The actual execution of the Meteorological Office experiment broadly confirmed previous expectations. It showed, for example, that the parameterisation of convective motions was not always realistic, and in areas of few observations the meteorological situation tended as a result to become dominated by motions on the scale of one or two grid lengths driven by convection. On the other hand in reasonably well observed regions the model did fairly well. It reproduced realistically the structure, development and motion of the westward-moving waves which are characteristic of the GATE area. The rainfall associated with the systems fell into the accepted pattern though amounts were generally less than observed. Figure 2 compares predicted mean 24-h rainfall amounts for the 10-d period September 4–14 with observed values. It shows that, in spite of the scanty observations, the model predicts reasonably well the N–S gradient of rainfall and the maxima near the coast.

Facilities and resources

The network of upper-air sounding stations in the land sectors of the GATE area is shown in Fig. 1 together with the network of special observing ships as arranged for the last phase of the experiment when oceanographic and boundary-layer measurements on the B/C scales were given high priority. All the ships were capable of making routine surface and upper-air meteorological observations and the 19 in the B/C-scale array made a wide variety of special meteorological and oceanographical measurements, 8 of these being equipped with weather radar. Of the 13 research aircraft, 9 were equipped as flying laboratories, a few such as the Meteorological Office Hercules being comprehensively equipped with radar, with an inertial platform, doppler wind-finding equipment and turbulence probes to make accurate measurements of winds and turbulent fluxes of heat and momentum, and with radiometers, cloud-sampling instruments and an onboard data-processing system.

Continual coverage of most of the GATE area by the newly-launched US geostationary satellite was crucial to the whole operation because it enabled weather systems to be kept under continuous surveillance and aircraft to be directed to the most significant of them. Additional coverage was provided by several American polar-orbiting satellites carrying cloud-imaging and temperature-sounding devices.

Most of the ships and aircraft operated from Dakar as a base where excellent harbour, airfield and other facilities were made available by the government of Senegal.

Planning and operational management

It was important to weld the resources into a closely integrated and coordinated international expedition working as a single team. In particular, it was necessary to ensure compatability and comparability between the different national observing systems so that instrumental differences should not mask the properties of the atmosphere that they were designed to measure. This was accomplished by earlier intercomparisons and calibrations of the systems carried by ships and aircraft.

This scientific coordination, together with many other difficult problems of planning, management and logistics, were the main responsibility of the International Scientific and Management Group (ISMG). This international team of scientists, working mainly in Bracknell for the previous three years, produced a detailed scientific and operational plan under the general guidance and instructions of an intergovernmental Tropical Experiment Board that committed resources on behalf of the various governments.

Altogether the experiment had to be carried out with the efficiency and professionalism of a sizeable military operation but with sufficient flexibility to take maximum advantage of the weather and to allow individual scientists and groups to carry out a wide range of experiments with as little mutual interference as possible.

Typical aircraft operation

In this section I describe a typical multi-aircraft mission carried out on one day in the middle of GATE to give some idea of the scale and complexity of such an operation.

From a detailed study of time-lapse pictures from the geostationary satellite (see Fig. 3) and all the relevant meteorological data that led to a forecast of convective activity in the B-scale area, an operation involving six aircraft was mounted on August 10, 1974 to study the structure and environment of a cloud cluster and, at the same time, to provide basic data for the boundary-layer, radiation and oceanographic sub-programmes. A seventh aircraft was used to drop sondes from 40,000 feet and obtain additional vertical profiles of wind and temperature between the B-scale ship array and the African coast.

The Meteorological Office Hercules, carrying the Airborne Mission Scientist and the Control Captain responsible for the coordination of all the aircraft in the exercise, arrived over the B-scale array at 1000. On the basis of satellite information received by this aircraft from the Control Centre in Dakar and radar observations of cloud from the USRS Oceanographer at the centre of the array, the Airborne Mission Scientist selected a suitable cloud cluster for detailed investigation. Three other aircraft, a US DC-6 and C-130, and a French DC-7, then arrived in the area and were joined later by two US jet aircraft, a Sabreliner and a Convair 990.

The first four aircraft flew 'butterfly' patterns at fixed levels between 550 feet and 16,000 feet above sea level, each involving two penetrations of the cloud cluster as shown in Fig. 4. This pattern was flown three times by each aircraft and involved penetration of the active cloud cores. Each aircraft recorded continuously its position, altitude, speed, and so on, the air temperature, humidity, radiation, sea-surface temperature (lower aircraft only) and the wind. Three aircraft carried gust probes to measure turbulent fluxes and a variety of cloud-physics instruments to determine liquid-water content, cloud- and rain-drop sizes, concentrations of condensation and freezing nuclei, and so on. When the radar aboard the aircraft and the USRS Oceanographer showed the cloud cluster to be moving quite rapidly westwards, the flight patterns were modified to allow for this drift. From 1245 to 1320 the Sabreliner made a high level reconnaissance at 39,000 ft above the other aircraft, and the Convair 990 flew the butterfly pattern three times at levels between 30,000 and 35,000 ft between 1300 and 1640. By 1550 the first aircraft was on its way back to Dakar but the last aircraft did not land until 1930 having spent 11 h in the air. Meanwhile, a US jet aircraft had dropped 14 sondes while flying on the track shown in Fig. 4 north of the B-scale area and around the Cape Verde Islands.

Data reduction and analysis

With the field phase of the experiment successfully accomplished, we now face the daunting task of processing and analysing the vast quantity of data collected. Some idea of its magnitude is given by the fact that the UK Hercules aircraft alone recorded some 10^9 words of meteorological data.

A detailed Data Management Plan, aimed at concluding the work within 2–3 years, prescribes in some detail schedules, procedures, methods and formats for the processing, checking, intercomparison and validation of the data and production of the final data sets in the form required by scientists working in the major programme areas and for input to numerical models.

Responsibility for reduction of the observations acquired on national platforms—ships, aircraft, satellites, and so on, lies primarily with the nations themselves but, because of the different systems and instruments employed, these will have to be compared and made consistent using the results of the intercomparison and calibration trials made during the experiment. These tasks of coordination and integration will be carried out at five centres, each being responsible for a particular sub-programme. Coordination between the five centres and monitoring of the whole programme will be carried out by a small group of scientists located in the WMO Secretariat in Geneva. Their task will end in 2–3 years' time with the deposition of the final data sets in the World Data Centres in Washington and Moscow where they will be available on demand to scientists throughout the world.

Mechanistic model for triple junction fracture geometry

S. Bhattacharji
Department of Geology, Brooklyn College of the City University of New York, Brooklyn, New York 11210
H. Koide
Geological Survey of Japan, Shinjuku-Ku, Tokyo, Japan

We show that fractures produced in an elastic, homogeneous lithospheric plate by stress generated by wedging of deepseated igneous mass(es) are comparable with the major fracture geometry and rift valley formation associated with the Red Sea, Gulf of Aden and East African Ridges; and that the formation and evolution of certain triple junction fracture geometry (FFR to RRR types) can also be related to stress generated around an oblate magmatic body.

GEOPHYSICAL data[1–4] from the Red Sea and Gulf of Aden indicate the presence of large mafic mass(es) in the central trough(s). In the northern Red Sea, between 17°N and 26°N, the Bouguer gravity anomaly map shows +100 mgal over the centre of the Red Sea with +125 to +150 mgal maximum[4]. This positive gravity anomaly extends over the northern Red Sea south of the Sinai Peninsula and probably as far south as 14°N though the magnitude is much less (Fig. 1). From these data we assumed the presence of a vertically elongated oblate igneous mass at depth extending along the axis of the Red Sea (Fig. 2) and the Gulf of Aden, and analysed the effects of magmatic stress caused by such bodies in producing rifting and fracture geometry (especially FFR to RRR types, where F denotes fault and R denotes ridge[5]) in the elastic lithospheric plates.

Basic data

We used Boussinesq's three-function method as described elsewhere[6–8] to obtain stress distribution(s) around fractures in an infinite and homogeneous elastic rock body. Isolated oblate magma bodies were assumed to exist in isotropic elastic lithospheric rocks in the Red Sea, Gulf of Aden–Carlsberge Ridge and along the East African Rift System. Although idealised, this assumption can be used as a first approximation, if the fractures are propagated essentially in a brittle manner. Because fractures are formed under high stress, the shape of the apex of the oblate ends and the curvature of the upwell or swell and vertical protrusions are considered more important for our theoretical analyses than points, lines or circular holes[9,10]. We analysed stress distributions around vertically elongated oblate igneous bodies of aspect ratios 1 : 10 to 1 : 1000, assuming that the magmatic upwell or igneous mass would continue to grow at depth in areas of asthenospheric plumes[11] or of partial melting. Details are presented elsewhere[7,8,12]. Our analyses show that the absolute magnitude

Southern Red Sea showing the probable formation of the Afar depression, *en echelon* normal faulting and graben, and the development of the Wonji fault belt at the axial region of the East African rift due to funnelling or bifurcation of the tensional fracture arm into strike-slip and/or *en echelon* arrays of tensile fracture zone(s) caused by stress from wedging of igneous masses into the lithospheric plate in the Gulf of Aden, Red Sea and East African ridge areas.

R381

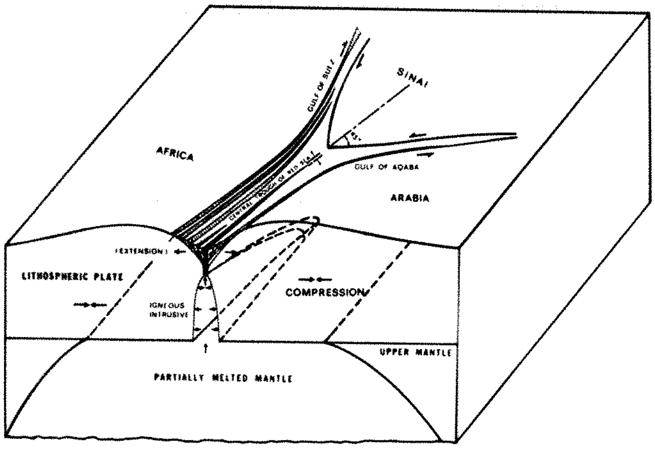

Fig. 2 The mechanism of formation of the central rift in the Red Sea and the FFR type triple junction fracture geometry at the northern end caused by wedging of the dike-like igneous mass into the lithospheric plate. Graben subsidence occurs along a set of funnel-shaped normal faults in the central zone of the rift valley. The areas of compression and extension are shown by arrows; wide domal uplift and relative subsidence in the central region, as deduced from the distribution of elastic displacement vectors are shown.

of the stress contours (Fig. 3) around the apex of an oblate igneous body varies slightly with the change in aspect ratio from 1 : 100 to 1 : 1000. The effect of changing the Poisson ratio of the lithospheric plate from 0.26 to 0.4 was negligible.

These analyses indicate that: (1) elastic stress concentration is greatest around the apex of an oblate shaped igneous body (Fig. 3); and that (2) a vertically elongated oblate body is an ideal shape for the diapiric uprise of magma[13] because wedging of such an igneous mass into the lithospheric plate produces wide areas of lateral compression at the sides at depth but causes horizontal extension within a funnel-shaped zone above the top (Fig. 2).

When magma fluid pressure exceeds lithostatic stress, maximum stress concentration at the apex of the oblate ends may initiate fracture propagation in the elastic lithospheric plate in areas of high stress concentration, along existing lines of weakness or inhomogeneous spots. This initiates FFR type[5] of triple junction fracture geometry (Figs 2–4) with a tensional arm in front of the tip (where later intrusion of magmatic dikes may result in a ridge) branching into two shear zones at an angle of 30–45° with the magmatic stress axis in an homogeneous plate (as the triple junction associated with East Pacific Rise in oceanic plate) and/or *en echelon* arrays of tension fractures associated with or extending along the fracture zones (Figs 2, 3). Although one arm of the shear zone may show transcurrent movement (as left lateral in the Gulf of Aqaba), the other bifurcating arm may show *en echelon* tensile fractures which, with increasing magmatic stress, give rise to continuous normal-faulted zones (the Gulf of Suez, Figs 1, 2). Displacement along the normal-faulted zones may produce subsidence and graben (Fig. 2).

Distribution of elastic displacements above the prolate end of the elongated magma body indicates a wide domal uplift, but an area of relative subsidence and graben would occur in the centre of the domal uplift above the prolate end (Fig. 2) producing an elongated rift valley (central trough) bounded by inward-dipping funnel-shaped normal or block faults as in the Red Sea area[12]. Where magma from deeper levels has wedged or intruded closer to the surface, the fractures (normal faulting) produced by magmatic stress extend upward and outward as in the Red Sea and Rhine graben areas[14,15]. Magmas (mafic or felsic) intruding as axial dikes through such fractures in the central rift zone would produce lateral stretching, further rifting and spreading. Intrusion of a wedge-shaped or slab-like mafic mass through the central normal fault zone would produce areas of relatively higher positive gravity anomaly within the trough and above the rift zone[2,4,14,16].

Our analysis also indicates that stress from broad doming or upwell is not itself great enough to produce axial collapse and rift valley formation of the magnitude of the Red Sea as was proposed by Cloos[17] in 1939. This has also been emphasised recently by Gass and Gibson[18]. Mechanistically, and based on magnetic, seismic and gravity data, the formation of rift valleys and their extension and branching can be explained by dyke-like intrusions of igneous masses into the lithospheric plate below the rift valleys (Fig. 2).

An estimation of stress concentration around prolate protrusions[6,7] above an oblate magma body shows higher stress concentration with increasing aspect ratios from spheroidal to vertically elongated protrusions, and the development of predominantly radial, radial–concentric and concentric fracturing respectively in the lithospheric plate around such pipes, necks or volcanic centres along the axis of the rift valley or normal-faulted zone.

Mechanistic interpretations

The bifurcation of the Red Sea rift at approximately 27°8′N into two shear zones, Gulfs of Suez and Aqaba (Figs 1, 2), the angle of about 45° of the Gulf of Aqaba shear arm with the NW–SE Red Sea axis[4], and the left lateral transcurrent movement of the Gulf of Aqaba–Dead Sea–Jordan shear zone[19–21] are consistent with mechanistic analyses of fracture formation as a result of the Red Sea mafic intrusive mass from the upper mantle (Figs 1–3). Magnetic anomalies and high-level oceanic crust are not present in the northern part of the Red Sea (beyond 25°N), but the central trough continues as a definite bathymetric feature northward toward Sinai where it seems to terminate against the left lateral transcurrent Jordan shear[4,18]. Mechanistically, this part represents a tensional arm (Figs 1, 2) not yet filled by oceanic (mafic) materials at the upper level of the Red Sea crust, bifurcating into normal-faulted shear zones south of Sinai (Fig. 2). This triple junction fracture geometry at the northern end of the Red Sea is interpreted as FFR type because it relates to stress at the apex of the vertically elongated igneous mass along the rift in the Red Sea, and not RRR

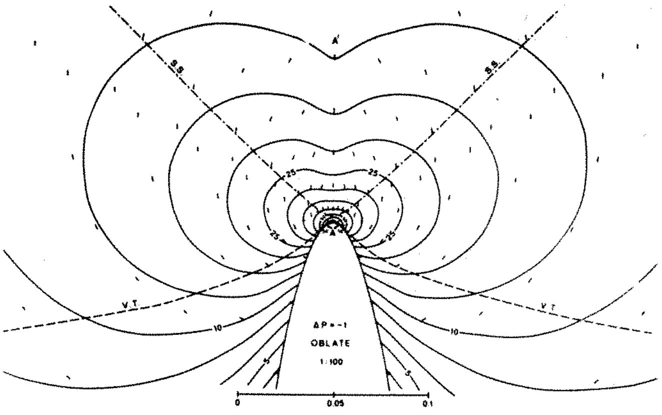

Fig. 3 Contour diagram of maximum tensile stress (in kbar) caused by an excess of magma pressure (P) over lithostatic stress (σ_1) ($P - \sigma_1 = -1$ kbar) around the apex of the dyke-like, oblate intrusive mass. Tensile stress is indicated as positive. Only the contours around the apex (area of maximum stress concentration) are shown. Lithostatic stress should be superimposed on the stress value(s) shown. The direction of maximum stress is perpendicular to the short lines. Above the line VT induced stress due to excess magma pressure is three-dimensionally tensile although absolute tensile stress actually occurs close to the tip of the intrusive mass.

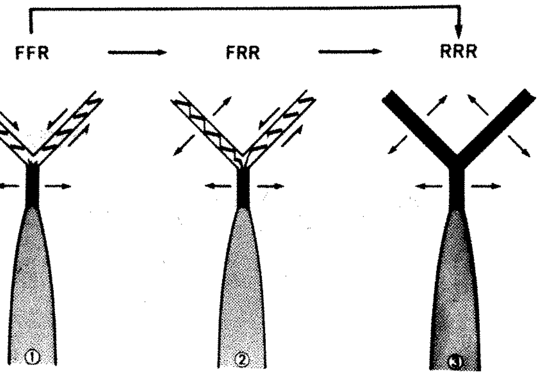

Fig. 4 Development of FFR type triple junction fracture geometry due to an oblate igneous mass and probable path of development of RRR from FFR type triple junction fracture from progressive increase of magmatic wedging and stress.

type with a hot spot at the centre of the triple junction south of Sinai as envisaged by Burke and Dewey[22]. Lack of igneous activity, and large negative gravity anomalies in the Gulfs of Suez (−50 mgal) and Aqaba (−100 mgal) support this interpretation. But continued rifting with increasing magmatic stress and filling of properly oriented fracture arms with magmatic materials can transform an FFR into an RRR type triple junction. This gradual evolution may follow the path FFR→FRR→RRR or proceed directly from FFR to RRR type (Fig. 4). The Gulf of Suez has been suggested to be a "failed arm"[22] of a triple junction; there is no geophysical evidence[4] of its continuation northward in the Mediterranean. On the other hand, the Gulf of Aqaba–Dead Sea–Jordan shear zone is more extensive (600 km) and shows transcurrent movement on the order of 90 to 110 km (refs 4, 20). The 45° orientation of the Gulf of Aqaba–Dead Sea–Jordan shear to the principal stress axis (Figs 1, 2) of the Red Sea igneous mass is ideal for strike-slip movement providing relief of the stress resulting from magma'pressure caused by continued magma generation at depth, rifting, magmatic wedging and spreading along the Red Sea central trough; it adds to the NE movement of the Arabian Plate[23]. This may also account for the low seismicity of the northern Red Sea. Mechanistically, the Gulf of Suez represents an *en echelon* fault zone widened (70–80 km) by normal faulting with continued rifting and increasing stress because of the growth of the Red Sea igneous mass since Miocene. The orientation at 10–15° of the Gulf of Suez to the principal Red Sea axis (Fig. 1) makes it an extensional inactive or "failed" arm of the northern Red Sea triple junction fracture. The orientation of preexisting lineaments in the basement rocks seems to have controlled the low angle orientation of this fracture zone producing the Gulf of Suez.

At the southern end of the Red Sea, the oceanic crust and centres of volcanism within the Red Sea rift seem to extend to almost 15°N (refs 4, 18; Fig. 1). On the basis of seismicity[23], however, the Red Sea rift has been considered as continuing further south to join with the Gulf of Aden and East African rift forming the boundary of the triple junction plates of Arabia, Nubia and Somalia. Mechanistically, the southern extension of the Red Sea central rift represents a tensional fracture arm, developed from stress resultant from further wedging and intrusion of the Red Sea igneous mass, which bifurcates into two shear-faulted tensional belts: the Gulf of Aden and the main Ethiopian rift (Figs 1 and 2). The Gulf of Aden, identified as a tensional feature[24], involves the separation of the continental blocks of Africa and Arabia and the formation of new oceanic crust in between. The belt of Quaternary tensional faulting occurring along much of the axial portion of the main Ethiopian rift, termed the Wonji fault belt[25], is characterised by a series of *en echelon* fracture swarms[26] and is interpreted by Gibson[27] as open tensional faults resulting from left-lateral shear along the length of the main Ethiopian rift. This and Girdler's view[28] agree with our mechanistic interpretation (Fig. 1) which suggests that the origin of the Wonji fault belt is related to stress from the Red Sea igneous mass. An axial zone of relatively high Bouguer gravity values coincides with the Wonji fault belt and injection of basaltic dikes at shallow depth has been suggested[29]. Thus, mechanistically, the triple junction fracture geometry (FFR) at the southern end of the Red Sea is being transformed to RRR type with magmatic wedging and intrusion in the Gulf of Aden and the main Ethiopian rift.

The Gulf of Tadjura represents a tensional feature (Fig. 1) produced by rifting as a result of the Gulf of Aden's magmatic stress. If its origin is related to this magmatic stress, the Gulf of Tadjura's tensional arm should bifurcate into two *en echelon* normal-faulted tensional or shear zones. These seem to be: one, paralleling the Red Sea along the western Danakil block and extending to the Gulf of Zulu; the other extending along the western margin of the Aisha block toward the Somalia Plateau (Fig. 1). Normal faulting toward Afar along these bifurcating fracture arms would produce the Danakil and Aisha Horsts (Fig. 1). Stress caused by the igneous mass along the East African ridges would cause bifurcation or funnelling into two *en echelon* normal-faulted zones (Fig. 1). Such funnelling of the East African ridges into the Dankelina fault along the Ethiopian side and the East African rift along the Somalia side is well known[30]. Normal faulting along the en echelon tensional zones of Ethiopia, Somalia and Danakil height [29] (Fig. 1) would produce a depression similar to Afar with a high plateau or horst on each side of the triangle. Thus the origin of the Afar depression can be directly correlated with the stress fields generated by the wedging of the Gulf of Aden and the East African igneous masses. At the northern end of the Ethiopian plateau and the Danakil height, the normal-faulted zone(s) narrow into the Gulf of Zulu (Fig. 1) and mark it as a tensional zone. Mechanistically, all the Gulfs (Suez, Tadjura, Zulu, and so on) are tensional features. Recent active rifting, spreading, volcanism and the formation of graben along the tensional zones within the Afar depression[31] may result from complex interaction of stress fields and fracturing in the Afar crust caused by the East African, Red Sea and Gulf of Aden's magmatic stresses.

The analysis also suggests that one need not invoke the presence of hot spots or asthenospheric plumes[22] at the intersection of triple junctions to explain every example of major or minor triple junction (FFR or RRR type) fracture geometry.

This work was partially supported by the NSF. We thank Dean M. Gabriel of Brooklyn College for additional support and computer facilities.

Climatic changes, Norsemen and modern man

W. Dansgaard, S. J. Johnsen, N. Reeh, N. Gundestrup, H. B. Clausen & C. U. Hammer

Geophysical Isotope Laboratory, University of Copenhagen, Haraldsgade 6, DK-2200 Copenhagen, Denmark

Oxygen isotope analysis of a new ice core from the crest of the Greenland ice sheet reveals a climatic record of the past 1,420 years. Climatic changes of medium frequencies are in phase with corresponding changes in Iceland and England, whilst long-term changes at mid Atlantic longitudes are out of phase with Europe and North America. Reconciliation with Norse history suggests a strong climatic impact, and a parallel is drawn to the present critical situation of the human society.

POLAR glaciers contain palaeoclimatic information in the form of varying isotopic composition of the ice, as given by the δ-function, the per mille (‰) deviation of the concentration of the heavy oxygen isotope ^{18}O in ice from that in Standard Mean Ocean Water[1-4]. During the precipitation process, the heavy isotopic component, $H_2{}^{18}O$, condenses preferentially (because its vapour pressure is slightly lower than that of $H_2{}^{16}O$), which causes decreasing δ in the vapour and subsequent precipitation at high latitudes as the cooling proceeds. Consequently, at a given location snow and ice deposited in summers or in warm climatic periods have higher δ than snow and ice deposited in winters or in cold climatic periods.

On this basis, continuous δ profiles along ice cores from the polar ice sheets have been interpreted in terms of seasonal or climatic variations. But the climatic interpretations have hitherto been hampered by a poorly determined relationship between δ and temperature variations. For example, a given long term change in δ along a deep ice core spanning many thousands of years may be partly caused by a change in surface altitude caused by a general climatic change[1-3]. The altitude effect is hardly important as regards intermediate ice cores (⩽400 m) from essentially stable parts of the ice sheet. Nevertheless, even in such cases, the temporal δ/temperature relationship is difficult to demonstrate directly, first because of the lack of reliable temperature records beyond the instrumental epoch, which only spans one century in Greenland, and less in other high polar regions, and secondly because short term climatic changes (periods shorter than 50 yr) are not completely equivalent in all parts of Greenland (Fig. 1).

Figure 1 shows observed temperatures in Godthaab (64°11′N, 51°45′W) on the West coast (heavy curves) and in Angmagssalik (65°36′N, 37°39′W) on the East coast (thin curves), smoothed by predictive low pass digital filter techniques removing all oscillations shorter than 10 years (to the left) and 30 years (to the right). The smoothing to the end of the record was accomplished by first extending the record using maximum entropy procedures[5]. The low pass filters have sharp frequency cutoff with insignificant influence from the side lobes. Generally, the short term oscillations are not in phase, and differences occur even in the 30-yr smoothed curves; for example the intermediate warming around 1960, only occurred on the West coast. Consequently, temperature records need further smoothing in order to reveal common features of Greenland climatic changes. This also holds for δ records along ice cores and this is why a 60-yr filter has been applied later in this work.

Obtaining the data

In the search for a representative area on the ice sheet, three drillings to 400 m have been made since 1971 by the Greenland Ice Sheet Program (GISP), an international joint effort with contributions by the USA, Denmark and Switzerland. The ice cores were recovered by the thermal drilling technique, and they are being studied by various analytical methods[6].

The first two GISP cores were recovered from DYE 3 in South Greenland (65°11′N, 43°50′W) and Milcent in central

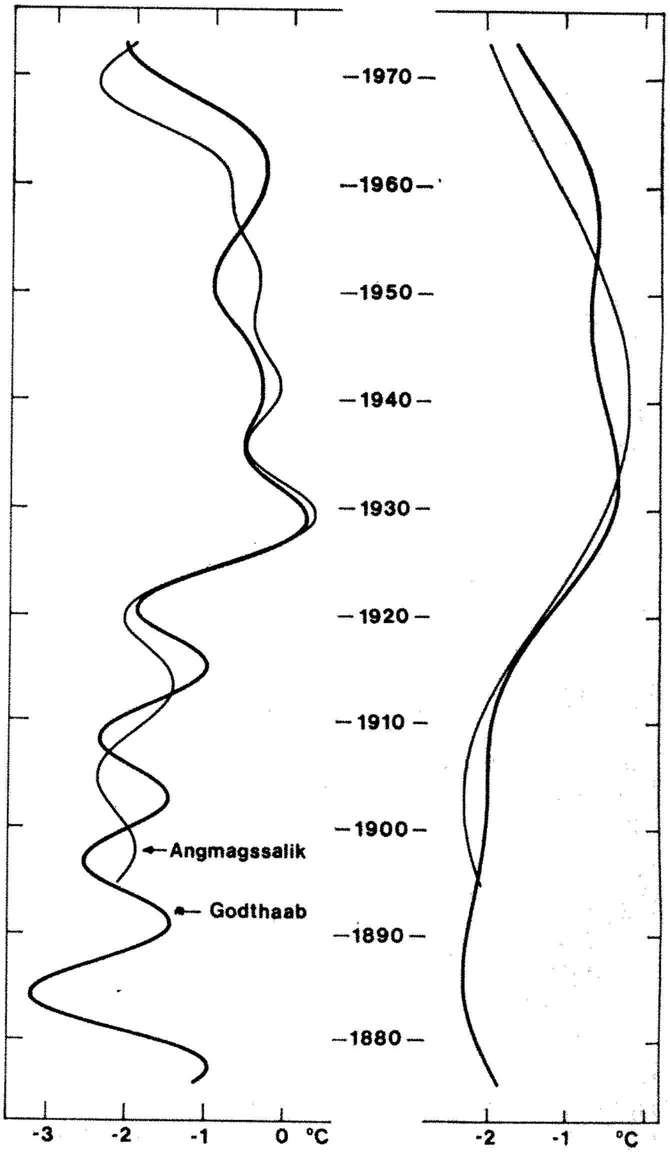

Fig. 1 Observed Greenland temperatures smoothed by 10-yr (left) and 30-yr (right) low pass digital filters. High frequency climatic changes do not always occur simultaneously on the West coast (Godthaab) and on the East coast (Angmagssalik).

Greenland (70°18′N, 44°35′W). Seasonal variations in δ were measured in a continuous sequence over the entire core length for the purposes of dating and accumulation rate measurement. Counting δ summer maxima downward from the surface leads to time scales along the cores that probably deviate less than 5% in the upper layers, and hardly more than 10 yr from absolute chronology at any depth. The oldest layer in the two cores dates from ~1232 AD and 1176 AD, respectively. The detailed plot of δ as a function of depth also gives the thicknesses of the individual annual layers. After corrections for vertical strain since the time of deposition, and for changing accumulation rate upstream, a smoothed plot of layer thickness as a function of time shows that the accumulation rate has kept surprisingly constant over the nearly eight centuries spanned by the cores[3]. This justifies the assumption made below of essentially constant accumulation rate at other locations in the same part of Greenland. In cases where no seasonal variations of δ have been measured, a time/depth relationship may be established by using the following formula[7] for the age t of an annual layer now situated y metres above the bedrock:

$$t = [(2H-h)/2a]\ln[(2H-h)/(2y-h)] \qquad y>h$$

a being the accumulation rate, H the thickness of the ice sheet, and h the value of y above which the horizontal velocity profile is assumed to be uniform. For values of H of the order of 2,000 m or more, h is not critical for the time scale over the upper 400 m. In the case of the DYE 3 and Milcent cores, application of the formula gives time scales that at any depth deviate less than 10 yr from the chronology obtained from seasonal variations of δ measured along the cores.

A third ice core 404 m long was recovered by GISP in the summer of 1974 at Crête on the crest of the ice sheet, 3,172 m above sea level, in Central Greenland (71°07′N, 37°19′W). A time scale based on seasonal variations of δ involves 16,000 measurements and has not yet been completed.

The ice flow pattern is, however, extremely simple in the Crête area, and the accuracy of the time scale defined by the formula is therefore expected to be even better than at DYE 3 and Milcent. With $H = 3{,}150$ m of ice equivalent[8], $h = 600$ m and $a = 0.287$ m yr^{-1} (measured by seasonal variations of δ in the upper layers and checked by β activity analyses), the formula shows that for $y = 2{,}770$ m, corresponding to the bottom of the bore hole, the core reaches 1,420 yr back in time. Accordingly, 1,420 samples were cut from the ice core, each one representing one calculated year of accumulation. The corresponding δ values (available on request) are of course not applicable for very short term considerations and were smoothed by a 60-yr low pass filter. The resulting record, spanning the time back to 554 AD, is shown in the left section of Fig. 2, with a per mille scale on top.

Temperature variations

The temperature scale for Godthaab, West Greenland, below the curve (Fig. 2) has been calculated by comparing the 0.9‰ δ shift from 1890 to 1935 with the corresponding 2.1 °C change in Godthaab temperatures (observed since 1876 and smoothed by a 60-yr low pass filter). Because of the short period of observation it is difficult to estimate the temperature/δ relationship very accurately, in spite of the correlation coefficient being as high as 0.94. With this reservation, and assuming that the δ curve is also closely related to Godthaab temperatures before 1876 (which it is to Iceland temperatures, see below), the δ curve may be read in terms of Godthaab temperatures at least through the seventeenth century and, most likely, over its entire time span.

The upper part of the mid section of Fig. 2 shows a record (smoothed the same way) of observed and estimated temperatures at Stykkisholmur, Iceland. For the 1590–1846 interval the temperatures were estimated[9] by considering the systematic observations of sea ice reported in the Icelandic annals. These observations were calibrated in terms of temperature by comparison with the Stykkisholmur temperatures through the period 1846–1966. The upper part of the smoothed δ record agrees (0.88 correlation coefficient) with the Iceland temperatures back to 1590 (significant at the $P=0.005$ level

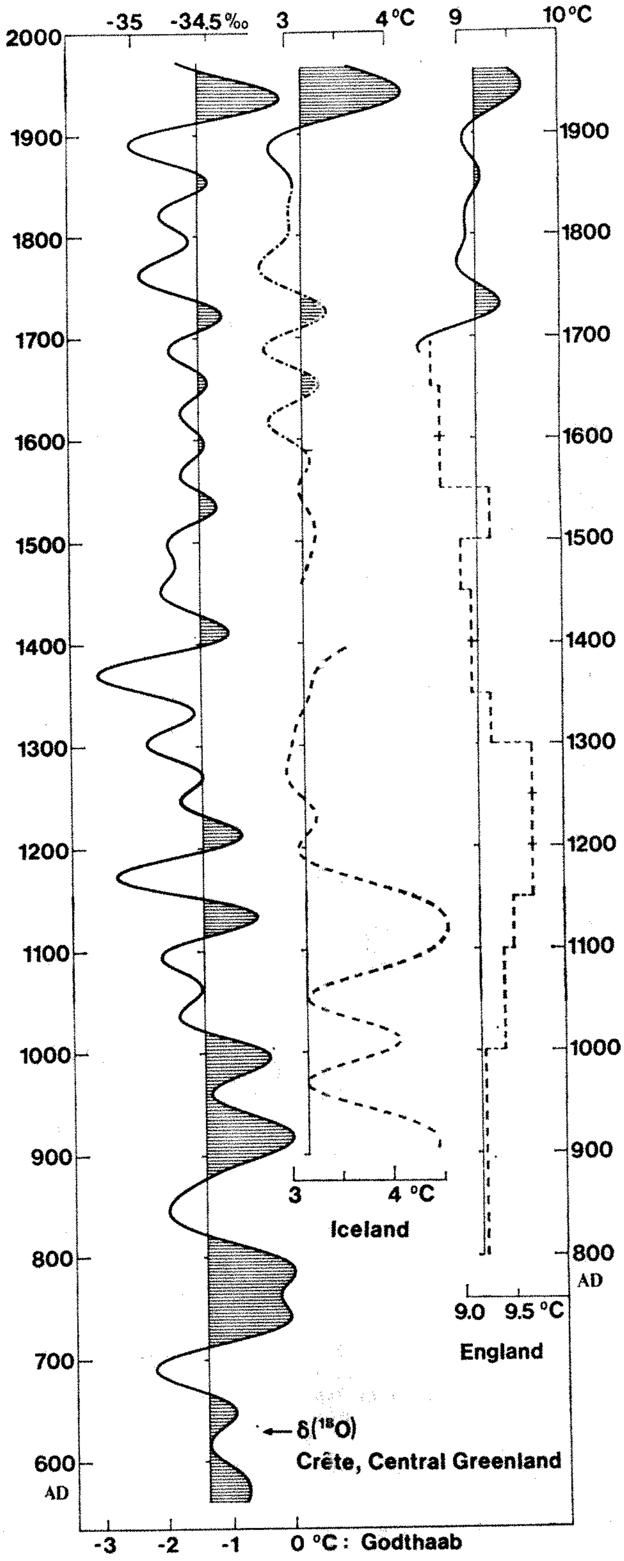

Fig. 2 Comparison between the ^{18}O concentration (left) in snow fallen at Crête, Central Greenland, (δ scale on top), and temperatures for Iceland and England. The curves are smoothed by a 60-yr low pass digital filter, except for England 800–1700 AD. The full curves are based on systematic, direct observations, the dashed-dotted part of the Iceland record is estimated from systematic ice observations[9], whereas the dashed curves depend on indirect evidence[9,14].

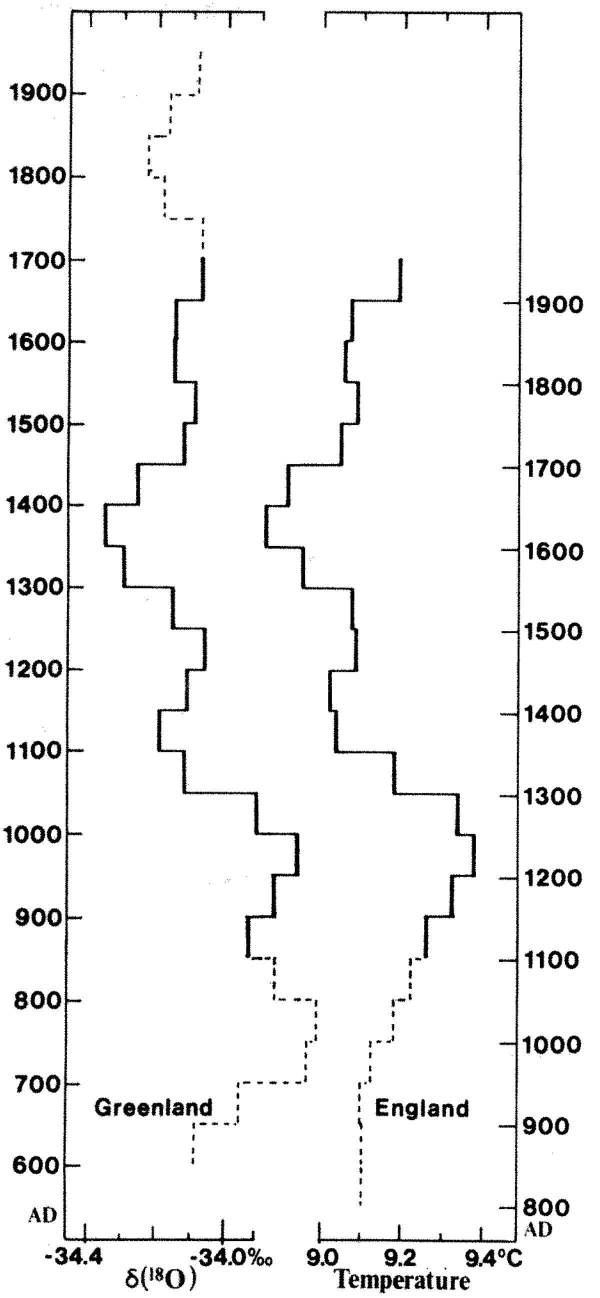

Fig. 3 Correlation since 850 AD between long term trends of 50-yr means of $\delta(^{18}O)$ in Greenland and temperature in England 250 yr later (notice different time scales). The data for England are those shown in Fig. 2, except that all oscillations shorter than 200 yr have been removed by a low pass digital filter. The data for Greenland have been treated accordingly.

with an estimated number of degrees of freedom $n = 7$). The regression coefficient is 1.4 ± 0.3 °C per 1 ‰ change in δ.

In England, temperatures have been measured more or less systematically since 1680 (refs 10, 11). The full curve in the upper right part of Fig. 2 shows this unusually long record smoothed by a 60-yr low pass filter. Comparison with the δ curve gives a correlation coefficient of 0.81 ($P = 0.02$, $n = 6$) and a regression coefficient of 0.8 ± 0.3 °C per 1 ‰ change in δ.

The significant correlation between the upper parts of the curves suggests that the δ curve is representative of climatic changes far beyond the Greenland area. But this conclusion applies only to the climatic changes of medium frequencies (60 to 200 yr periods) that strongly dominate the records through the recent centuries (for short periods, the δ curve is barely representative for the whole of Greenland, see Fig. 1). Changes of lower frequencies that are obvious in the δ curve prior to 1500 AD must be compared with records based on indirect evidence.

Other climatic indicators

In the mid section of Fig. 2 the 60-yr smoothed Iceland curve before 1590 is derived[9] from occasional information in Icelandic annals about sea ice, mild or severe winters, years of good or bad crops, and so on. In spite of the lack of direct meteorological evidence, most of the pronounced medium frequency oscillations back to 900 AD are essentially in phase with the δ curve. The annals[12] tell about very cold years 1367–79, but only little about sea ice. Though not reflected by the dashed curve (Fig. 2), this cold period may be reconciled with the δ-minimum late in the fourteenth century. For the fourteenth century as a whole, there are different opinions among Icelandic historians. Some claim[13] that it was colder than the thirteenth century. Very little information is available from 1400–1470, when the country was afflicted by famines and bubonic plague; but the essential agreement between several details in the two curves is an interesting consequence of the inveterate literary tradition in the early Icelandic society, culminating with the sagas that were written about 1100–1300 AD.

A similar extension of the temperature curve for England is shown in steps before 1700 AD to the right in Fig. 2. It is estimated from various kinds of historical information of meteorological significance[14]. In the 1100–1700 AD interval each step represents 50 yr, and before 1100 AD only two estimates are given; one for the eleventh century and another for the preceeding two centuries. Therefore, the curve only allows considerations of long term climatic trends (periods longer than 200 yr).

The twelfth and thirteenth centuries were extremely warm in England. This must be considered a well established fact, especially since it is substantiated by palaeobotanical evidence; for example, according to ref. 14 vines were grown commercially in England from 1000 to 1300 AD (which suggests even higher temperatures than the more direct meteorological evidence). In fact, the period of extreme warmth may have begun earlier, since there were several vineyards in England before 1000 (H. H. Lamb, personal communication). Thus, the time of the onset of the mediaeval warmth is more uncertain than the time of its termination, which took place around 1300 AD, 100–150 yr later than in Iceland at longitude 20°W, and 250–300 yr later than at Crête at about 36°W.

Furthermore, it is striking that the cold period from 1450 to 1700, often called "the little ice age", was not particularly cold at Crête or in Iceland. The Crête counterpart may be found some 300 yr earlier, from about 1150 to 1400. Nor does "the little ice age" of 1450–1700 stand out clearly in the Milcent (44°W) δ profile. On the other hand, it appears in δ profiles further West at Camp Century[1] (61°W) and in tree-ring records from the White Mountains, North America[15] (119°W). In the latter profile the mediaeval warmth also appears in phase with Europe.

So long term climatic changes at mid-Atlantic longitudes seem to be out of phase with similar changes in Europe and in North America. The phase shift between Crête and England is further illustrated in Fig. 3 showing sequences of 50-yr means smoothed by a 200-yr low pass filter. Apart from the relatively uncertain lower part of the England curve, the variation in temperatures in England from 1100 to 1950 are parallel to the 850–1700 part of the Crête δ curve with a correlation coefficient of 0.92 ($P = 0.01$, $n = 6$). Cross spectra show essentially the same 250-yr time lag and a very high coherence for all oscillations longer than 200 yr. This shows that, within the last millenium, long-term climatic changes have occurred 250 yr later in West Europe than in Greenland.

The data do not, however, enable any conclusion to be drawn about the persistency of the time lag over long spans of time because the high value of n used above, and the consequent high confidence level, is chiefly a result of a cycle close to 250 yr in each series. This cycle is in phase in the cross spectrum of the synchronous series, and will, of course, be so in any cross spectrum of the series displaced by multiples of 250 yr. If the time series in Fig. 3 were smoothed by a 400-yr low pass filter, the correlation coefficient would still be high (0.99), but not significant ($P = 0.10$, $n = 3$). Thus, the upper, dashed part of the δ curve in Fig. 3 may, at most, suggest a general cooling trend in West Europe within the next century. There are other reasons why caution should be applied in this respect. For example, the actual climatic changes in the past 300 yr have been dominated by oscillations of higher frequencies than those considered in Fig. 3; and man-made pollution of the atmosphere may completely change the picture.

A possible explanation for the delay of the shift from the mediaeval warmth into "the little ice age" may be found by considering the quasi-stationary Rossby waves (disturbances of the general circumpolar westerly winds in the upper troposphere, caused by blocking anticyclones) the position of which determines the meridional wind components. If the average wavelength of the Rossby waves increased (perhaps because of a varying radiation balance), it may have caused a slow eastward displacement of the climatic belts in the Northwest Atlantic region, at the same time as a southward displacement of the polar front may be responsible for the general cooling of the Northern Hemisphere. A changing gross wind pattern would influence the course and the intensity of the Gulf Stream, running in between the two areas considered here, which would enhance the climatic effect.

Norse history

With due consideration of the probable 150 yr time lag between the end of the mediaeval warmth in Greenland and Iceland, it is tempting to try to reconcile the δ curve in Fig. 2 with some well documented important events in the early Icelandic and Norse societies. The Norwegian farmer Floke Vilgerdson made the first attempt to settle in Iceland in about 865 AD, during a short cold period. He lost his cattle in a severe winter and disappointed went back to Norway after having seen "a fjord filled up by sea ice. Therefore, he called the country Iceland" (Landnam Saga, about 1200 AD). Only a few years later, in 874, Ingolf Arnarson succeeded. He was followed by many others, and landnam (settlement) was completed in 930 AD. The δ curve suggests that the landnam was favoured by a considerable and rapid climatic warming late in the ninth century.

In 982, Erik the Red discovered new land West of Iceland. He called it Greenland; according to the Greenlander Saga this was only to persuade people to follow him, when he founded the Østerbygd in South Greenland in 985. But the δ curve suggests that the name described a reality, since Erik came to Greenland at the end of a warm period longer than any that has occurred since. The suspicions of the author of the Greenlander Saga may be explained by the long term climatic deterioration reaching Iceland 150 yr later than Greenland.

So, the drastic climatic change late in the ninth century may be part of the reason why Iceland and Greenland did not get the opposite names, which would have been more natural had they been discovered simultaneously.

The cold fourteenth century marked the beginning of the tragic end of the Norse society in Greenland. Shortly before 1350 the Vesterbygd in the Godthaab Fjord died out, and some 100 yr later the Østerbygd as well. The reason is not clear. The early hypothesis about degeneration by endogamy[16] rested on flimsy evidence, because only a few skeletons from the fourteenth and fifteenth centuries have been found; this is in itself peculiar in view of the hundreds of skeletons known from before 1300. A possible reason is that the increasing permafrost in the soil forced the late Vikings to change their burial customs. The δ curve suggests that the climate became so cold in the fourteenth century that years of famine must have occurred frequently, as was the case in Iceland, particularly in the 1370s (ref. 12). On the other hand, the cold made whaling a good business for European mariners who may have assaulted the Østerbygd—at least, eskimo tales blame pirates for the extinction of the weakened Norse society. Nor can it be excluded that the plague, which came to Iceland in 1402 (ref. 12), was transferred to Greenland by pirates.

Present and future climate

The dying out of the Greenland colony has fascinated generations of historians, maybe because it is the only example of a well developed European society being completely extinguished in historical time. But quantitatively it was a rather insignificant event compared to what has happened in other parts of the world—and happens today. Few of these tragedies can be ascribed to climatic changes alone, but the impact of climate on human life stands out more and more clearly, particularly where the margin of survival is slim, whether in the polar regions or in the tropics.

The warm period in the present century has culminated. In fact, most of the climatic improvement from 1920 to 1935 seems to have been lost, and although the average cooling of the Northern Hemisphere since 1940 has only been[17] of the order of 0.4 °C, it is highly significant. For example, it has reduced the growing season in England by a week or two[14] and there are indications that the small changes of the meridional temperature gradients may have induced recent disastrous events in the tropics[18].

This stresses the question of whether the future will bring back the favourable climatic conditions that prevailed in part of this century, or will remain closer to the cooler conditions that characterised most of the past six centuries or more. On the face of it, the recent warm peak was an unusual event.

The problem is, however, too important to be treated only in a speculative manner, the more so as man-made pollution of the atmosphere is now introducing new climatic parameters. Climate modelling will undoubtedly lead to a deeper understanding of the mechanism behind climatic changes and, hopefully, to the reliable climatic prognoses so badly needed for learning the consequences of man's continued impact on the environments, and for rational planning of his future activities.

In this context, the significance of palaeoclimatic records lies primarily in the need for diagnosing the processes that cause climatic changes, and for checking the validity of the models on all time scales between 10 and 10^6 yr. The record shown here offers such a possibility only for the 30–10^3 yr interval, but extension of the record 5×10^5 yr back is merely a matter of drilling deeper in Central Greenland. Nowhere else in the world is it possible to find a better combination of reasonably high accumulation rate (which ensures continuity of the record), simple ice flow pattern (which facilitates the calculation of the time scale), high ice thickness (which offers a detailed record, even at great depths) and meteorologically significant location (close to the main track of North Atlantic cyclones). This is why GISP has selected the Crête area for the drilling to the bedrock planned for 1977.

Several people contributed to the success of the GISP 1974 field season, and we are indebted to all of them: Robert Rutford and Karl Kuivinen of the GISP Management Office, University of Nebraska–Lincoln; John Rand, Lyle Hansen, Steve Mock and Chester Langway of US Army CRREL; A. Herr and P. Schmucke, Squadron VXE-6, U.S. Navy; Hans Oeschger, Bernhard Stauffer and Henry Rufli, University of Bern; Jan Nielsen and Nils Andersen, University of Copenhagen; S. E. Wølk, Danish Arctic Contractors; and Poul Madsen, Scandinavian Airlines System, Sdr. Strømfjord. We also thank W. Hibler III, H. H. Lamb and J. Namias for reading the manuscript.

This research was supported by US National Science Foundation, Office of Polar Programs; The Danish Natural Science Research Council; and the Ministry of Greenland, Copenhagen.

Modified nucleosides and bizarre 5′-termini in mouse myeloma mRNA

Jerry M. Adams & Suzanne Cory

The Walter and Eliza Hall Institute of Medical Research, PO, Royal Melbourne Hospital, Victoria, 3050, Australia

Messenger RNAs from mouse myeloma cells contain N^6*-methyl adenosine and novel 5′ termini having 7-methylguanosine in a 5′,5′triphosphate linkage with ribose-methylated nucleosides. Ten common 5′-terminal sequences of the forms* $m^7G^{5'}ppp^{5'}NmpNp$ *and* $m^7G^{5'}ppp^{5'}NmpNmpNp$ *are reported. Structures like this may be a general feature of mRNA in eukaryotes.*

ALTHOUGH most messenger RNAs (mRNAs) of eukaryotes are known to contain a 3′-terminal poly(A) sequence[1], no other distinctive structural features of the molecules have been identified. Almost nothing had been known about the 5′ termini, and the mRNAs were believed to contain only the four standard nucleosides, until Perry and Kelley[2] showed that mRNA from mouse L cells contains a very low level of methylated nucleosides, involving methylation of both base and ribose moieties. As it seems very likely that the rare modified nucleosides have some critical roles, we have investigated the modified residues in the poly(A)-containing mRNA from mouse myeloma cells, using a simple fingerprinting technique. We found that the pattern of modification of mRNA is very different from that of ribosomal RNA (rRNA) or transfer RNA (tRNA), that a prominent modified nucleoside in mRNA is N^6-methyladenosine, and that modified residues occur in both 5′- and 3′-terminal regions of the RNA. Our most significant finding is that the mRNAs have 5′-terminal structures of an unexpected kind, in which 7-methylguanosine and ribose-methylated nucleosides are linked by three phosphates in such a way that the terminal 7-methyl guanosine is 'inverted' with respect to the rest of the molecule. We report here ten sequences of this kind representing the 5′ termini of a large fraction of myeloma mRNAs. Related 5′-terminal structures, first found in three small nuclear RNAs of unknown function[3,4], have now also been identified in animal viral mRNAs (refs 5–8), and evidence suggests they exist in other cellular mRNAs (ref. 9). Structures of this new form may prove to be a general feature of mRNA in higher organisms.

Detection of modified nucleotides

P1 (ref. 10) or MPC 11 (ref. 11) myeloma cells were labelled in culture with ^{32}P-orthophosphate and total RNA was extracted from postnuclear (experiment 1) or postmicrosomal (experiments 2–4) supernatants. The mRNA was separated from rRNA and tRNA by two cycles of adsorption to oligo(dT)-cellulose[12] and then glycerol gradient centrifugation (see legend to Fig. 1). The RNAs were then digested with a mixture of ribonucleases[13] which produces nucleoside 3′-monophosphates (Np) from internal positions and nucleoside di-, tri-, or tetraphosphates (pNp, ppNp, or pppNp) from RNAs with 5′-terminal phosphates. The digests of RNAs containing 2′-ribose methylations will also include dinucleotides (NmpNp) or oligonucleotides ($\mathrm{Nmp(Nmp)_nNp}$), since the phosphodiester bond adjacent to a 2′-O-methyl group is resistant to the ribonucleases used. The nucleotides were fractionated by a simple modification of the Sanger fingerprinting procedure[14], involving electrophoresis on cellulose acetate at *p*H 3.5 and then on DEAE paper at the same *p*H (ref. 15).

A typical fingerprint of mouse myeloma mRNA is shown in Fig. 1*a* and is illustrated diagrammatically in Fig. 1*b*. In addition to the four major mononucleotides, a number of minor components can be seen, including a mononucleotide (designated *m1*), two prominent dinucleotides (*d1* and *d2*) and, most striking, a group of spots (*o1*–*o12*) near the top of the fingerprint in positions expected for tetra- or pentanucleotides. The fingerprint is clearly different from those of 28S and 18S rRNAs, which are characterised by high levels of many dinucleotides (Fig. 2*a* and *b*) and from that of myeloma tRNA, which contains a great variety of modified mononucleotides (Fig. 2*c*). No oligonucleotides are produced from 18S rRNA (Fig. 2*b*) or tRNA (Fig. 2*c*) and only two from 28S rRNA ('tri' and 'tetra' in Fig. 2*a*).

Bizarre 5′-terminal sequences

From the position of *o1*–*o12* on the fingerprint, the oligonucleotides were expected to contain a cluster of at least three 2′-O-methyl nucleosides (for example, NmpNmpNmpNmpNp) or to contain one or more 5′ phosphates with correspondingly fewer 2′-O-methyl nucleosides (for example, ppNmpNmpNp)—the former could be derived either from 5′ ends of the molecules or internal positions, the latter only from 5′ termini. The first type of structure was excluded when digests of the oligonucleotides were found to contain too few 2′-O-methyl nucleotides (see below). The second type was excluded when we found that alkaline phosphatase released only the 3′-terminal phosphate from each oligonucleotide and that each contained four (or less frequently, five) 'internal' phosphates. Thus we were forced to consider some much more unusual structure. One possibility was suggested by the report[3,4] that three small nuclear RNAs have 5′-terminal structures involving a previously unknown 5′,5′ diphosphate linkage,

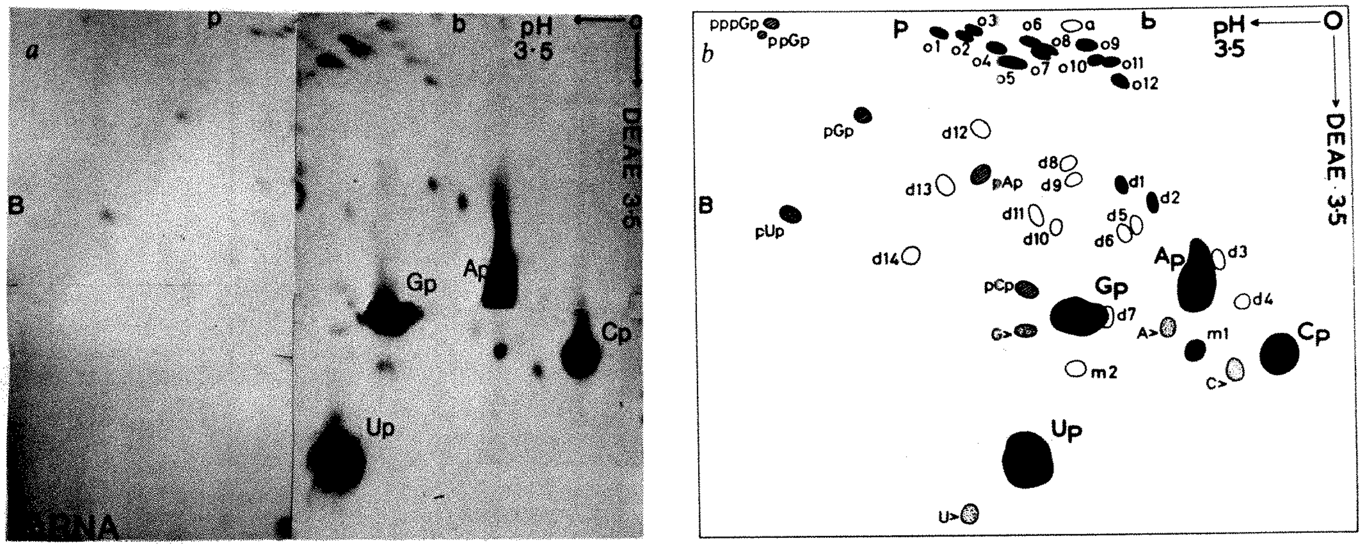

Fig. 1 Two-dimensional electropherogram of complete enzymic digest of myeloma mRNA: (*a*) 17 h autoradiograph and (*b*) schematic diagram. Poly(A)-containing RNA (35×10^6 c.p.m., 60 μg, including carrier tRNA) from a postmicrosomal supernatant of MPC 11–66.2 cells was digested for 6 h at 37 °C in 30 μl 15 mM ammonium acetate, *p*H 4.5, 2 mM EDTA with 7 μg pancreatic RNase (Worthington), 7 μg T1 RNase (Sankyo) and 20 units T2 RNase (Sankyo). The digest was vacuum dried, dissolved in 6 μl water, and subjected to high voltage electrophoresis (5 kV, Gilson Electrophorator) at *p*H 3.5 on a strip (3×90 cm) of cellulose acetate (Oxoid) in 7 M urea, 5% acetic acid, 0.5% pyridine and 2 mM EDTA until the orange G marker dye had migrated 60 cm (about 4 h)[14]. The region of cellulose acetate from the origin to just beyond the orange G marker was used for the second dimension. The nucleotides were blotted[14] on to two sheets of DEAE paper (one 46×90 cm, the other 23×90 cm), and after the sheets were washed with 70% ethanol and dried, were subjected to electrophoresis at 1.1 kV in 5% acetic acid and 0.5% pyridine (*p*H 3.5) until the xylene cyanol FF (blue) marker dye had migrated ~20 cm (about 15 h). The stippled spots in (*b*) correspond to nucleoside 2′-, 3′-cyclic phosphates. The spot marked (a) is an artefact caused by a trace of Gp sticking at the origin on the DEAE paper. *m2* is presumably also an artefact since it was absent from other fingerprints of mRNA. The letters p and b indicate the mobility of acid fuchsin (pink) and xylene cyanol FF marker dyes, respectively, in the first dimension, and B the mobility of xylene cyanol in the second dimension. Cells were labelled and poly(A)-containing RNA was isolated as follows: 1,500 ml roller cultures of MPC 11–66.2 (ref. 11) or P1Bu1 (ref. 10) cells were grown at 37 °C in Dulbecco's modified Eagle's (DME) medium (Gibco) supplemented with 10% heat-inactivated foetal calf serum (Biocult) to 4.5×10^5 ml^{-1}. The cells were then harvested by centrifugation at 2,000 r.p.m. for 5 min (Sorvall GS3 rotor), resuspended at $5–7\times10^5$ cells ml^{-1} in phosphate-free DME medium (Gibco) supplemented with 10% heated horse serum (Biocult), and incubated at 37 °C for 3 h before addition of 50 mCi of carrier-free ^{32}Pi. After 16.5 h of labelling, which gave 30% incorporation of ^{32}Pi into TCA-precipitable material, the cultures were poured on to crushed frozen isotonic buffer, the cells harvested by centrifugation, and RNA isolated by one of two procedures. (a) Cells were lysed at 0 °C by resuspension at 10^7 ml^{-1} in 0.3% NP40, 0.13 M NaCl, 0.02 M Tris-Cl (*p*H 7.5), 7.5 mM magnesium acetate, 2 mM DTT and 0.15 M sucrose[16], and nuclei were removed by centrifugation at 0 °C for 5 min at 3,000 r.p.m. (Sorvall SS34 rotor). After a further centrifugation of the lysate at 12,500 r.p.m. for 10 min, the supernatant was adjusted to 15 mM EDTA and 0.2% SDS and digested at 0 °C for 10 min with 0.3 mg ml^{-1} proteinase K (Merck, chromatographically pure)[17]. The digest was then made 0.1 M in Tris-Cl, (*p*H 9.0) and 1% in SDS, and extracted three times at room temperature with an equal volume of phenol–chloroform–isoamyl alcohol (50:50:1, vvv)[18]. RNA was precipitated from the aqueous phase by the addition of 2.5 volumes of ethanol and then precipitated twice more from 0.2 M NaCl, 0.02 M Tris-Cl (*p*H 7.5) and 2 mM EDTA. (*b*) Cells were resuspended at 20×10^6 ml^{-1} in ice-cold hypotonic buffer (0.01 M KCl, 0.01 M Tris-Cl (*p*H 7.5) and 1.5 mM MgCl$_2$) and, after 10 min at 0 °C, were broken by nine strokes with a B pestle in a Dounce homogeniser. Ionic conditions were adjusted by the addition of 0.4 volume 2.0 M sucrose containing 62.5 mM KCl, 0.15 M Tris-Cl (*p*H 7.5) and 13.75 mM MgCl$_2$ and nuclei were removed by centrifugation as above. Microsomes were removed by sedimentation at 30,000 r.p.m. (Beckmann Type 30 rotor) for 20 min through a cushion of 5.75 ml 0.8 M sucrose in 0.1 M KCl, 0.05 M Tris-Cl (*p*H 7.5) and 5 mM MgCl$_2$ (ref. 19). The entire post-microsomal supernatant was diluted twofold with distilled water, then digested with proteinase K and extracted as in (*a*). Poly(A)-containing RNA was separated from bulk RNA by two cycles of oligo(dT) chromatography at 30 °C. RNA was applied at 3–4 A_{260} ml^{-1} in 0.3 M NaCl, 0.1% SDS, 0.01 M Tris-Cl(*p*H 7.5) and 2 mM EDTA to a (1×2 cm) column of oligo(dT)–cellulose[12]. The column was then washed thoroughly with starting buffer followed by 0.2 M NaCl, 0.01 M Tris-Cl (*p*H 7.5) and 2 mM EDTA. The poly(A)-containing RNA (~ 1×10^6 c.p.m. μg^{-1}), representing about 2% of the A_{260}, was then eluted with 0.01 M Tris-Cl (*p*H 7.5) and 2 mM EDTA, rechromatographed as above, and finally precipitated with ethanol in the presence of carrier tRNA. The RNA was dissolved in KTE buffer (0.01 M KCl, 0.01 M triethanolamine-Cl (*p*H 7.5) and 1 mM EDTA, heated to 65 °C for 5 min[19], chilled rapidly and then sedimented at 40,000 r.p.m. (Beckmann SW 40 rotor) for 12.5 h through a 10–30% glycerol gradient in KTE buffer. Small amounts of material sedimenting at the same positions as marker 28S and 18S rRNAs and very small amounts less than 9S in size were discarded, and the remaining RNA was recovered by ethanol precipitation and reprecipitated twice more before digestion.

for example, m$_3$G$^{5'}$pp$^{5'}$AmpUmpC in the U2 RNA, where m$_3$G is N^2,N^2,7-trimethylguanosine[4,21].

We have now established that the oligonucleotides in mRNA have structures of the forms m^{7}G$^{5'}$pp$^{5'}$NmpNp and m^{7}G$^{5'}$ppp$^{5'}$NmpNmpNp, that is, 7-methylguanosine linked through its 5′ carbon by three phosphates to the 5′ carbon of a 2′-O-methylnucleoside, followed in some sequences by a second 2′-O-methylnucleoside, and then by an unmodified nucleoside (Fig. 3). Note that since the linkage of 7-methylguanosine and the first 2′-O-methylnucleoside is 5′, 5′ rather than the 3′, 5′ of conventional phosphodiester bonds, the 7-methylguanosine has a free 3′ hydroxyl.

The evidence for these structures, which can occur only at the 5′ termini of the mRNAs, will be presented elsewhere but in part is as follows: (1) Limited digestion of each oligonucleotide with venom phosphodiesterase, which only readily attacks oligonucleotides having a 3′-hydroxyl[22], released 7-methylguanosine 5′-phosphate, that is by the scission m^{7}G$^{5'}$p/pp$^{5'}$Nmp Np or m^{7}G$^{5'}$p/pp$^{5'}$NmpNmpNp. This indicates that the m^{7}G has a free 3′ hydroxyl and is linked through its 5′ phosphate. Moreover, this cleavage exposed two 5′ phosphates on the other product (pp$^{5'}$NmpNp or pp$^{5'}$NmpNmpNp), since alkaline phosphatase now released 3 mol Pi from it. Thus the m^{7}G is joined to the rest of the oligonucleotide by a 5′, 5′ triphosphate linkage. (2) Nucleotide pyrophosphatase, which liberates N^2, N^2, 7-trimethylguanosine 5′ phosphate from the related structures in the small nuclear RNAs[3,4], cleaves 7-methylguanosine 5′phosphate from the oligonucleotides, giving the same products as above. (3) Complete digestion of each oligonucleotide with venom phosphodiesterase after removal of the 3′ phosphate gives the expected products: pm^{7}G from the 5′ end, a pN from the 3′ end, either one or two pNm from internal positions and

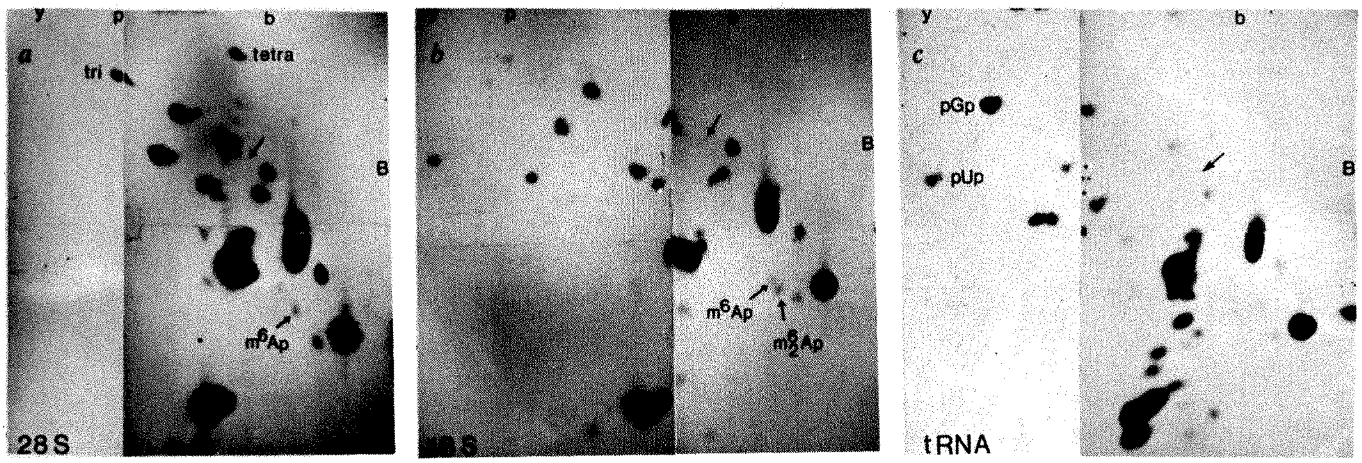

Fig. 2 Two-dimensional electropherograms of complete enzymic digests of (*a*) 28S rRNA (60 μg); (*b*) 18S rRNA (60 μg); (*c*) tRNA (30 μg) from MPC 11-66.2 myeloma cells. Digestion and electrophoresis conditions were as described in Fig. 1 and autoradiography was for 17 h. 28S, 18S and 3-8S RNA fractions were prepared by glycerol gradient centrifugation of the RNA which did not absorb to oligo(dT)-cellulose (see legend to Fig. 1). The 28S and 18S rRNA fractions (specific activity ~ 2.7×10^5 c.p.m. μg^{-1}) were purified further by a second gradient centrifugation. The tRNA was purified by subjecting the 3-8S RNA fraction to electrophoresis on a 10% polyacrylamide slab gel and extracting the entire region of the gel containing molecules 70–90 nucleotides in length[20]. Y indicates the mobility of the orange G dye marker in the first dimension and those of the other dyes are indicated as in Fig. 1.

Pi (for example, $m^7G^{5'}p/p/p^{5'}Nm/pN$). The digests also frequently contained some ppNm, which is compatible with a triphosphate but not a diphosphate linkage. For instance, digests of dephosphorylated *o5* contained pm^7G, pU, pCm, Pi and some ppCm, so we assign it the structure $m^7G^{5'}ppp^{5'}CmpU$.

Rottmann *et al.*[9] have recently proposed related structures for oligonucleotides from L cell mRNA: *XppNmpNp and *XppNmpNmpNp, where *X is an unidentified blocking group, possibly a nucleoside of 7-methlyguanosine type in 5′,5′diphosphate linkage with either one or two 2′-O-methyl nucleosides.

We have determined the sequences of the ten most common 5′-terminal oligonucleotides from myeloma mRNA (Table 1) and we have tentative sequences for ten others (J.M.A. and S.C., unpublished). In every sequence, the 5′-terminal nucleoside seems to be 7-methylguanosine and no derivatives of m^7G, such as the trimethylguanosine of the small nuclear RNAs[4,21], have been detected. The m^7G is in 5′, 5′ triphosphate linkage in all the sequences and none having a diphosphate linkage has been detected. All four standard 2′-O-methylnucleosides are present and a fraction of the 2′-O-methyladenosine in oligonucleotides *o6a*, *o9* and *o10* seems to contain a modified base. No evidence of other base modifications has as yet been found.

The relative molar frequency of the oligonucleotides is also given in Table 1. Clearly certain sequences are much more abundant than others; the most common sequence, $m^7G^{5'}ppp^{5'}$ CmpUp, represents about 20% of the modified termini and this and four other sequences constitute about 60% of these end groups. Sequences having one ribose methylation are much more abundant than those with two (about 6:1) but a number of the minor sequences are of the latter type (J.M.A. and S.C., unpublished). The 2′-O-methylnucleoside involved in triphosphate linkage can be any of the four standard ones, but sequences with Cm, Am, and Gm in this position are much more prevalent than those with Um. The relative frequency of 5′ termini in mRNA from microsomes seems to be similar to that in mRNA from postmicrosomal supernatants.

The proportion of mRNAs containing the oligonucleotides can be assessed from the data in Table 2, which gives their yields (and those of other modified nucleotides) expressed as mol per 10^4 residues and mol per 1,600 residues. The latter is an estimate for the number average size of the myeloma mRNAs based on the measured fraction (9.3%) of the mRNA radioactivity present in poly(A) sequences (average of four experiments) and a number average size of 150 residues for the labelled poly(A) determined by polyacrylamide gel electrophoresis in 8 M urea. The overall yield of the oligonucleotides has varied between 0.53 and 0.86 mol per 1,600 residues in four mRNA preparations, probably depending on the intactness of the mRNA. Since the yield was close to 1 mol per

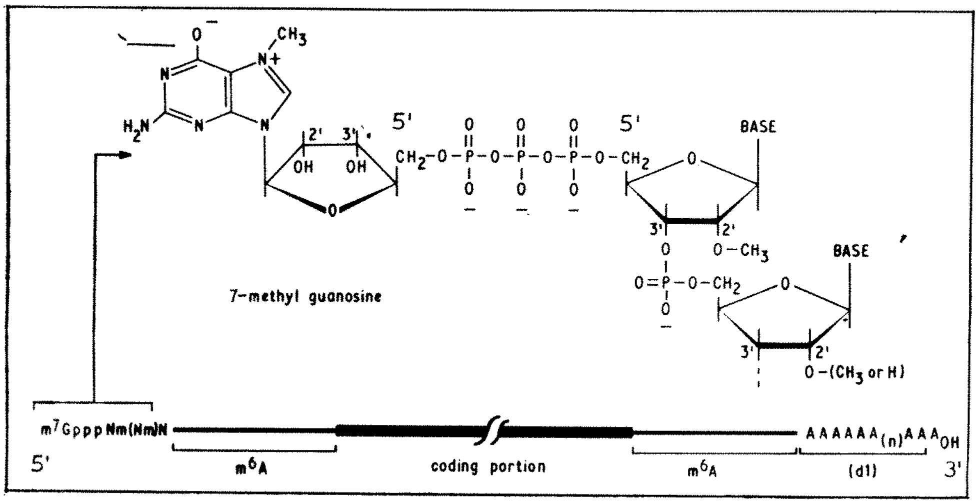

Fig. 3 5′-Terminal structure and possible location of the major modified nucleosides in myeloma mRNA. Note that the assignment of m^6A to two positions in the diagram may not mean that every molecule has two residues of m^6A. *d1* is shown in parentheses since only a fraction of the molecules contain it (see Table 2).

1,600 residues in two mRNA preparations (experiments 3 and 4 in Table 2), however, we conclude that a very large fraction of myeloma poly(A)-containing mRNAs (probably all) contain one of these modified 5′-terminal sequences. This conclusion is weakened only if the average size of the mRNA is actually much less than 1,600 residues, which seems unlikely. Most estimates for the average size of mRNAs in mammalian cells are in fact higher than this[23–26].

Since there can be no more than 1 mol of a 5′-terminal oligonucleotide per chain, the amounts of these products found in experiments 3 and 4 enable us to set an upper limit of about 1,900 residues for the number average size of the myeloma mRNAs. Setting this upper limit does not require our conclusion concerning the proportion of the mRNAs having modified 5′ termini.

Nucleoside diphosphates (pNp) have also been detected in the mRNA digests (Fig. 1*b*), but the yields have been very variable and were lowest in the two mRNA preparations in which the highest yields of oligonucleotides were found (Table 2). Therefore it seems likely that these 5′-end groups are derived primarily from mRNA which has been degraded either *in vivo* or during its isolation. A fraction of the pNp may be an artefact of the digestion (or other procedures), since we found some spurious pAp in digests of poly(A). Traces of ppGp and pppGp (Fig. 1*b*) were found in two experiments but not in two others (Table 2). No other ppNp or pppNp has been detected.

Other modified nucleotides

We have identified the prominent modified mononucleotide *m1* in Fig. 1*b* as N^6-methyladenylic acid (m^6Ap). A nucleotide in exactly the position of *m1* in fingerprints of 28S and 18S rRNA (Fig. 2*a* and *b*) was known to be m^6Ap (refs 27–29 and J.M.A. and S.C., unpublished) and *m1* had the same mobility as this nucleotide[30] on thin layer chromatography in five solvent systems. Since our procedures do not involve the alkaline conditions which produce m^6A from N^1-methyladenosine (m^1A)[31] and did not produce m^6A from m^1A in myeloma tRNA, it is clear that the mRNA contains the N^6-derivative. The average yield of m^6Ap is 1.3 mol per 1,600 residues (Table 2), so every mRNA could contain at least one residue of m^6A. No other modified mononucleotides have as yet been detected in mRNA digests, although our procedures reveal at least a dozen of the modified mononucleotides in tRNA digests (Fig. 2*c*). Since completion of this work, Desrosiers *et al.*[32] have reported that m^6A (and/or m^1A) is the only prominent nucleoside with a methylated base in Novikoff hepatoma mRNA.

Dinucleotides *d1* and *d2* (Fig. 1), isolated in submolar amounts from mRNA (Table 2), are not standard NmpNp. No product corresponding to *d1* occurs in rRNA or tRNA (arrows in Figs 2*a–c* indicate where *d1* would be). *d1* is alkali-stable and our analysis to date suggests the structure N*mpAp, where N*m is an unusual 2′-O-methylated adenosine derivative. *d2* is in the position of AmpAp but lacks a 2′-O-methyl ribose since it is hydrolysed by alkali, giving Ap and Xp, where Xp probably contains a modified adenine (not m^6A, m_2^6A, or the base present in *d1*).

Dinucleotides *d3–d14* in Fig. 1 are the standard NmpNp found in high yield in rRNA (refs 15, 27, 28, 33 and J.M.A. and S.C., unpublished). Since they were virtually absent in two mRNA preparations, *d3–d14* clearly come from rRNA. The level of NmpNp thus provides a quantitative chemical index of contamination by rRNA, which we calculate to be about 2.5% in the mRNA used in Fig. 1*a* but less than 0.5% in experiments 3 and 4 of Table 2.

If we arbitrarily assign *d1* and *d2* one methyl group each, we can calculate from the yields of all the products so far detected (Table 2) that myeloma mRNA contains about 2.0 methylated nucleosides per 1,000 residues. As this is very close to the 2.2 ^3H-methyl groups per 1,000 residues found in mouse L cell mRNA (ref. 2), it seems likely that the major methylated nucleosides in the mRNA have been accounted for.

Table 1 Common 5′-terminal sequences in myeloma mRNA

Oligonucleotide	Structure*	Relative molar frequency† of modified termini
o5	$m^7Gp^{5'}pp^{5'}CmpUp$	21%
o7	$m^7Gp^{5'}pp^{5'}GmpCp$	11%
o6a‡	$m^7Gp^{5'}pp^{5'}AmpGp$	12%
o6b‡	$m^7Gp^{5'}pp^{5'}GmpAp$	6%
o3	$m^7Gp^{5'}pp^{5'}GmpGp$	8%
o12	$m^7Gp^{5'}pp^{5'}CmpCp$	5%
o8§	$m^7Gp^{5'}pp^{5'}CmpUmpCp$	6%
o1	$m^7Gp^{5'}pp^{5'}GmpUp$	5%
o10	$m^7Gp^{5'}pp^{5'}AmpCp$	5%
o9	$m^7Gp^{5'}pp^{5'}AmpAp$	4%
	Total	83%

*The derivation of the sequences will be reported elsewhere (S. Cory, and J. M. Adams, unpublished).

†The relative molar frequency was calculated from the data in Table 2.

‡The analysis of *o6* indicated the presence of the isomers in a ratio of about two to one.

§The analysis of *o8* indicated the presence of $m^7Gp^{5'}pp^{5'}CmpUmpCp$ but did not exclude the presence of $m^7Gp^{5'}pp^{5'}UmpCmpCp$ as well.

Preliminary location experiments

We have carried out two types of experiments to map the positions of m^6A, *d1* and *d2* within the mRNA molecules. In the first, mRNA was treated with 0.1 M NaOH for 4 min at 0 °C, which gave on average about one scission per molecule; 3′-terminal poly(A)-containing 'halves' (and residual intact molecules) were then separated from 5′-terminal 'halves' by passage through oligo(dT)-cellulose. In the second, mRNA was digested to completion with T1 RNase (which splits after Gp residues) and oligo(dT)-cellulose was used to separate the poly(A) fragments, which include a few residues before the poly(A) sequence[34,35], from oligonucleotides derived from the rest of the molecule. Each of the four sets of fragments was then fingerprinted as described previously.

The results obtained were consistent with the model shown at the bottom of Fig. 3. As expected, all the oligonucleotides were enriched in the 5′-terminal 'halves' and completely absent from the 3′-terminal T1-poly(A) fragment. *d1* was present only in the two sets of fragments containing poly(A) and moreover, was present in a fragment from which all residues preceding the poly(A) sequence had been excised with pancreatic RNase. Thus *d1* must be contiguous with or within the poly(A) sequence. Neither m^6A nor *d2* was present in the T1-poly(A) fragments, but m^6A (and apparently *d2*) was present in similar amounts in both 5′- and 3′- 'halves'. Conceivably, m^6A may be located within the coding portion of the molecule, but as its hydrogen bonding properties[36,37] may interfere somewhat with translation, we favour a location within the non-coding regions of mRNA, which are thought to include a 5′-terminal region and a region preceding the poly(A) sequence[1,38].

Significance

In summary, poly(A)-containing mRNA from mouse myeloma cells contains at least eight kinds of modified nucleosides, including 7-methylguanosine, N^6-methyladenosine, the four standard ribose-methylated nucleosides and smaller

*Molar yields were determined by measuring the radioactivity in the paper containing each nucleotide in a scintillation counter, dividing by the total radioactivity in all the products, and correcting for the number of phosphates per nucleotide shown in parentheses in the first column. In practice, to compensate for some variability in the transfer of Cp to DEAE paper, we related the yield of each minor nucleotide to Up and multiplied by a factor determined from the known frequency of Up (23.35%), measured by an independent method.

†Experiment 1 is a digest of poly(A)-containing RNA from a post nuclear supernatant of P1Bu1 myeloma cells prepared by procedure (*a*), (see legend to Fig. 1). The yields were measured for two separate digests of the same RNA preparation and have been averaged except where they differed by more than 25%.

‡Experiments 2, 3 and 4 are digests of poly(A)-containing RNA from post microsomal supernatants of MPC 11-66.2 myeloma cells, prepared by procedure (*b*) (experiment 2; see legend to Fig. 1), or by a modification of the double detergent procedure[16] (experiments 3 and 4). The fingerprint for experiment 2 is shown in Fig. 1*a*.

§The much higher yield of pNp in the second fingerprint of the same mRNA preparation is probably caused by some artefactual production of new 5′-terminal phosphates (see text).

ND, not detected.

amounts of two unidentified components (in *d1* and *d2*). A myeloma mRNA of 1,600 nucleotides contains three to four modified residues, possibly arranged as shown at the bottom of Fig. 3. The 7-methylguanosine and the standard 2′-O-methylnucleosides are found only in 5′-terminal structures, where they are joined in an unexpected 5′, 5′ triphosphate linkage. Since the 7-methylguanosine is thus 'inverted' with respect to the remainder of the chain, the mRNAs, surprisingly, have free 3′- and 2′-hydroxyls at each end of the molecule. At least 20 and possibly 30 different modified 5′-terminal sequences are present in myeloma mRNA, but all seem to be of the two forms m^{7}G$^{5'}$ppp$^{5'}$NmpNp and m^{7}G$^{5'}$ppp$^{5'}$NmpNmpNp, with the former occurring much more frequently. Ten sequences accounting for about 80% of the 5′ termini have been determined and certain sequences are found to greatly predominate, with five of the known sequences representing about 60% of the total.

The various modified 5′ termini in mRNA may assume different physical structures. Base stacking and other interactions between the 7-methylguanosine and the different 2′-O-methyl nucleosides would be facilitated by the additional flexibility of a 5′, 5′-triphosphate bridge[39]. Presumably the unusual charge properties of 7-methylguanosine[40] influence the structures.

The modified 5′-termini provide the first chemical marker for this region of mRNA. Moreover, the presence of 2′ and 3′ hydroxyls on the terminal nucleoside permits labelling of 5′ termini with ^{3}H-borohydride[4,5] and should allow other reactions normally restricted to 3′ termini of RNA molecules[41].

5′-Terminal structures identical in form to those described here have very recently been identified in animal viral mRNAs synthesised *in vitro*. Furuichi *et al.*[5] report that all the mRNAs made by reovirus particles in the presence of the methyl donor S-adenosyl-methionine contain the sequence m^{7}G$^{5'}$ppp$^{5'}$GmpCp and mRNAs synthesised similarly by particles of the insect cytoplasmic polyhedrosis virus (CPV), which also has a double-stranded RNA genome, have m^{7}Gp$^{5'}$pp$^{5'}$AmpGp[6]. Moreover, Wei and Moss[7] have shown that the mRNAs made by particles of vaccinia virus, which has a DNA genome, have the 5′-terminal sequences, m^{7}G$^{5'}$ppp$^{5'}$GmpNp and m^{7}G$^{5'}$ppp$^{5'}$AmpNp, although the same sequences with a diphosphate linkage have been suggested by others[8].

We suspect that 5′-terminal structures of this new form will prove to be a general feature of mRNA in many, if not all, eukaryotic cells and for a variety of viral mRNAs. It seems probable that these complex structures are required for some general process(es) concerning mRNA, such as processing from precursors, transport to the cytoplasm or translation. The viruses cited above replicate in the cytoplasm, so we infer that at least one function of the structures is in a cytoplasmic process. Since there is very high sequence specificity in the methylation of RNA (refs 42 and 43), a considerable number of methylating enzymes presumably is required to generate the variety of methylated 5′-terminal sequences found in the cellular mRNA; this suggests that the particular modified sequences at the 5′ termini are important in their function. They may, for example, serve to 'tag' mRNAs (or mRNA precursors) to be handled in different ways.

The terminal 5′, 5′ linkages in mRNAs cannot, of course, be formed by normal transcriptional events; they must instead form by a special 5′, 5′ condensation reaction between a 5′-phosphorylated guanosine derivative and another nucleotide or polynucleotide, probably also 5′-phosphorylated. For some viral RNAs this reaction occurs during transcription. The modified 5′ termini of CPV mRNA (ref. 44) and probably also reovirus mRNA (refs 5 and 45) are formed on very small nascent chains by a reaction in which the 7-methylguanosine and adjacent phosphate originate from GTP and the other two phosphates from the NTP initiating chain formation[6]. Both ribose and base methylations seem to be closely coupled to the condensation reaction[5].

The reactions involved in the formation of the modified 5′ termini of cellular mRNAs are not known, nor is it even established whether they occur in the nucleus. Seemingly the reactions must differ from those for the viral mRNAs cited above, which are formed in the cytoplasm as primary transcription products. The mRNAs of mammalian cells are thought to be derived from 3′-terminal portions of longer precursors among the heterogeneous nuclear RNAs (ref. 1); the cleavage of the precursor would thus produce a mRNA segment lacking the 5′-terminal pppN . . . sequences of primary transcripts[46]. Conceivably the ribose methylation of mRNA precursors marks the site for this cleavage and the 5′, 5′ condensation reaction occurs either during or subsequent to the cleavage (see also refs 5 and 9). Since the location of mRNA sequences near the 3′ termini of nuclear precursors is not firmly established, however, the possibility that the 5′-terminal sequences in the mRNAs correspond to the 5′ termini of primary transcripts, as in the viral mRNAs, cannot be completely excluded.

We thank Drs T. S. Ro-Choi, A. J. Shatkin and C. M. Wei for providing manuscripts; Drs R. Cotton and M. D. Scharff for strains; Dr A. W. Harris for help with culture conditions; Drs L. R. Finch, K. D. Shortman and A. W. Harris for comments on the manuscript; and R. Muller and H. Simpson for assistance. This work was supported by grants from the

5′-Terminal 7-methylguanosine in eukaryotic mRNA is required for translation

S. Muthukrishnan, G. W. Both, Y. Furuichi & A. J. Shatkin

Roche Institute of Molecular Biology, Nutley, New Jersey 07110

Unmethylated reovirus and VSV mRNAs are specifically methylated to form 5′-terminal structures of the type, m^7G (5′) ppp (5′) N by protein synthesising extracts prepared from wheat germ and mouse L cells. Reticulocyte mRNA also contains 5′-terminal m^7G. mRNAs having 5′-terminal m^7G stimulate protein synthesis in vitro. *Removal of m^7G by β-elimination abolishes translation of the mRNAs.*

REOVIRUS and vesicular stomatitis virus (VSV) mRNAs synthesised *in vitro* by their virion-associated RNA polymerase in the presence of S-adenosyl-methionine (SAM) contain the 5′-terminal structures, $m^7G(5')ppp(5')G^m$ (ref. 1) and m^7G (5′) ppp (5′) A^m (ref. 2), respectively, and no other methylated nucleotides. The mRNAs are translated with fidelity in a wheat germ cell-free protein synthesising system[3,4], and their messenger activity is unaffected by addition to the extract of SAM or its analogue, S-adenosyl-homocysteine (SAH)[5]. Viral mRNA made in the absence of SAM also promotes the synthesis of authentic viral polypeptides *in vitro*; this was shown to be due to the ability of the wheat germ extract to methylate the viral mRNAs since translation of unmethylated viral mRNA was enhanced by addition of SAM to the extract but completely blocked by the inhibitor of methylation, SAH[5]. To determine if the methylation of mRNA required for translation is specific, we have analysed reovirus and VSV mRNAs after incubation in cell-free protein synthesising extracts. The viral mRNAs are methylated exclusively at the 5′ termini and the resulting 7-methyl-guanosine (m^7G) is essential for translation. Similarly, rabbit reticulocyte mRNA contains 5′-terminal m^7G and its removal by β-elimination results in the loss of translational activity *in vitro*.

5′-Terminal methylation of mRNA

Reovirus mRNA was synthesised with α-^{32}P-CTP as radioactive precursor in the presence of SAH to minimise methylation during transcription[6]. The 5′ termini of reovirus mRNA synthesised in these conditions are predominantly ppG . . ., but some of the molecules (~ 25%) have blocked, unmethylated 5′-terminal GpppG (our unpublished results). Purified, ^{32}P-labelled mRNA was incubated in a wheat germ cell-free extract with methyl-^3H-SAM in conditions of protein synthesis as described previously[3–5]. The mRNA was extracted with phenol, separated from 4S RNA by density gradient centrifugation[5], digested with *Penicillium* nuclease and alkaline phosphatase and analysed by high voltage paper electrophoresis[1]. All the ^3H derived from methyl-^3H-SAM by methylation of the RNA migrated as a single component in the region characteristic of blocked 5′-terminal structures[1,7] (Fig. 1*a*). No ^3H-labelled nucleosides were detected, consistent with the absence of methylated residues within the RNA chains. The enzymatic digestions were complete as shown by the quantitative recovery of the ^{32}P as Pi. The presumptive 5′-terminal material was analysed by DEAE-cellulose column chromatography and had a net negative charge of −2.5 (Fig. 1*b*, inset). The same charge was found for m^7GpppG^m isolated from the 5′ termini of methylated reovirus mRNA. When analysed by paper chromatography, however, the presumptive 5′ termini (peak I) migrated more slowly than marker m^7GpppG^m (Fig. 1*b*). Treatment of the peak I material with nucleotide pyrophosphatase converted all the radioactivity to 7-methylguanylic acid (m^7pG); no 2′-O-methylguanylic acid (pG^m) or other methylated nucleotides were detected (Fig. 1*c*). Alkaline phosphatase treatment after pyrophosphatase digestion converted the radioactivity to m^7G (Fig. 1*d*). The identity of both m^7pG and m^7G was confirmed by paper chromatography as described previously[1]. The results indicate that in the presence of SAM, wheat germ extract methylates the 5′ termini of reovirus mRNA, yielding m^7GpppG. This blocked, methylated structure is similar to the 5′-terminal sequence of reovirus mRNA methylated during transcription[1], but with the notable absence of 2′-O-methylation.

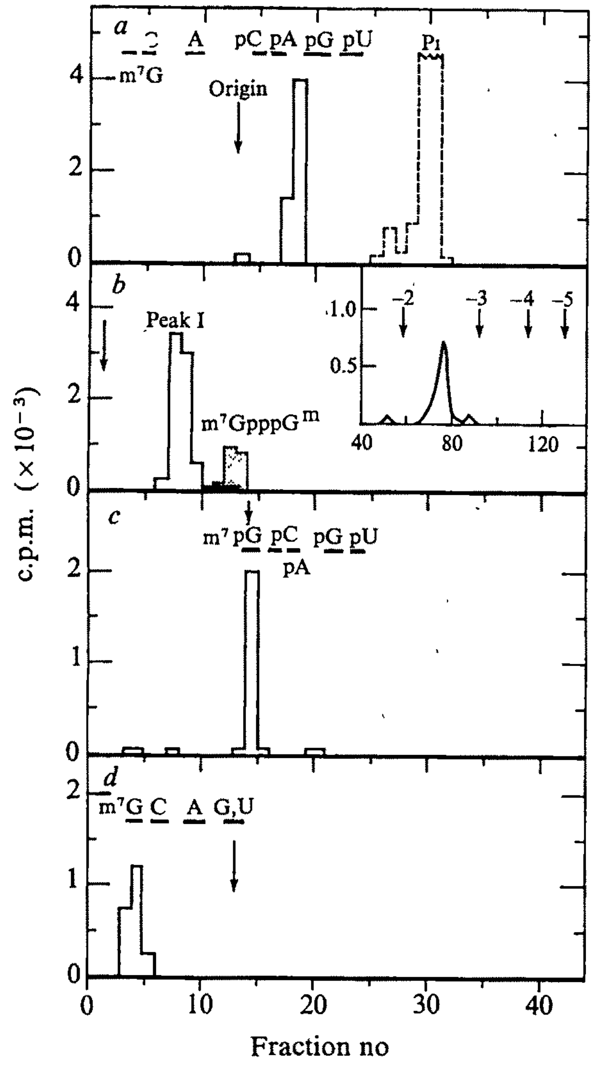

Fig. 1 Methylation of 5′ termini of reovirus mRNA by wheat germ extract. Reovirus mRNA (20 μg) synthesised in the presence of α-^{32}P-CTP and 10 μM SAH was incubated for 20 min in wheat germ cell-free protein synthesising extract containing methyl-^{3}H-SAM (2 μM, 7.3 Ci mmol^{-1})[3,5,6]. ^{32}P-labelled viral mRNA was recovered by phenol extraction and glycerol gradient centrifugation[3]. *a*, After treatment of the RNA with *Penicillium* nuclease followed by alkaline phosphatase, the digest was analysed by high voltage paper electrophoresis (pyridine acetate, *p*H 3.5, 2600 V, 40 min)[1]. *b*, The enzyme-resistant ^{3}H-labelled material in *a* was eluted and analysed by descending paper chromatography in isobutyric acid: 0.5N NH_4OH (10:6 v/v). Inset: an aliquot of peak I material was mixed with 20 A_{260} of a pancreatic RNase digest of yeast tRNA and applied to a 1×20 cm column of DEAE-cellulose equilibrated with 0.05 M Tris buffer, *p*H 8, containing 7 M urea. The column was eluted with a gradient of NaCl (0.0–0.3 M). Samples of 1 ml were counted in methyl-cellosolve and toluene-based scintillant[7]. The arrows represent the positions of the oligonucleotide markers as determined by absorbancy. *c*, Peak I material was digested with nucleotide pyrophosphatase and analysed by paper electrophoresis[1]. *d*, Peak I material was treated with a mixture of nucleotide pyrophosphatase and alkaline phosphatase and analysed by electrophoresis. The papers were dried, cut into 1 cm strips, and counted in toluene-based scintillation fluid[1].

To determine if VSV mRNA is also methylated at the 5′ terminus by wheat germ extract, ^{32}P-labelled viral mRNA was synthesised *in vitro* in the absence of SAM; in these conditions the 5′ termini of the transcription products are GpppA (ref. 8). The RNA was purified and incubated in the wheat germ cell-free system with methyl-^{3}H-SAM. After *Penicillium* nuclease plus alkaline phosphatase digestion of the repurified VSV mRNA, a single ^{3}H-labelled component which migrated toward the anode was obtained by paper electrophoresis (Fig. 2*a*). Paper chromatography of this presumptive 5′-terminal material again revealed that it migrated more slowly than marker m^{7}GpppA^m, the 5′-terminal structure of VSV mRNA methylated by the virion-associated enzyme[2] (Fig. 2*b*). Digestion with nucleotide pyrophosphatase and alkaline phosphatase converted all the ^{3}H-labelled material to m^{7}G and, as in reovirus mRNA, no 2′-O-methylated nucleosides were obtained (Fig. 2*c*). The structure of the m^{7}G was confirmed by paper chromatography. Thus, in the presence of SAM, reovirus and VSV mRNAs are methylated exclusively at the 5′ ends by wheat germ extract, yielding the 5′-terminal structures, m^{7}GpppG and m^{7}GpppA, respectively.

The translation of animal virus mRNAs in wheat germ extracts represents a heterologous system, and it was interesting to determine whether cell-free extracts from uninfected animal cells also contain viral mRNA methylating activity. Mouse L cells were used since they replicate reovirus, and cell-free extracts prepared from them have been shown to translate reovirus mRNA[9,10] and VSV mRNA (G. W. B., A. K. Banerjee, and A. J. S., unpublished results). An L cell protein synthesising S10 extract[10] was incubated with ^{32}P-labelled, unmethylated reovirus mRNA and methyl-^{3}H-SAM. The mRNA was methylated as shown by glycerol density gradient centrifugation, and the kinetics of methylation were similar to those observed with the wheat germ extract[5] (data not shown). The *Penicillium* nuclease plus alkaline phosphatase digestion products of the methylated mRNA isolated from the L cell extract were analysed by paper electrophoresis (Fig. 3*a*). The ^{3}H-labelled, presumptive 5′-terminal material migrated between pA and pG,

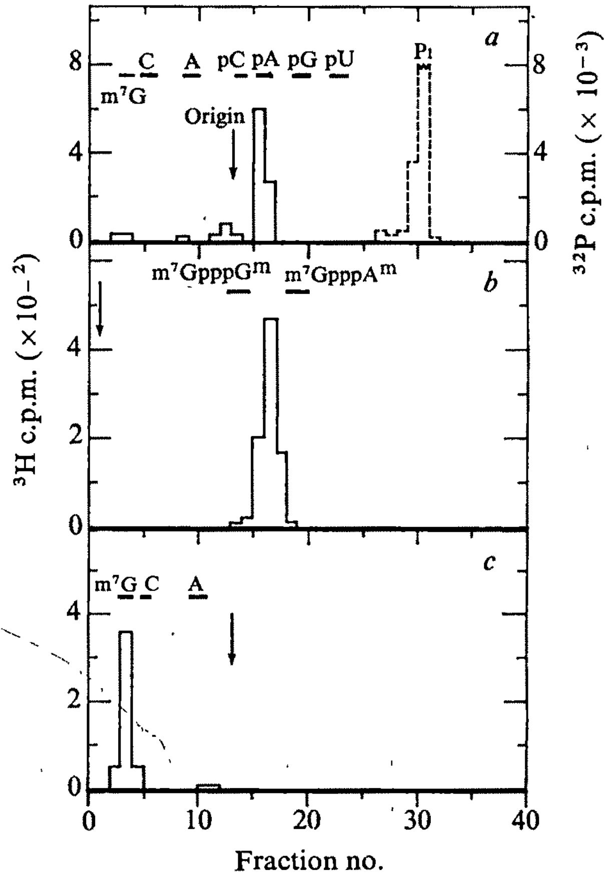

Fig. 2 Methylation of VSV mRNA 5′ termini by wheat germ extract. VSV mRNA (5 μg) synthesised *in vitro*[20] in the presence of α-^{32}P-GTP was incubated with methyl-^{3}H-SAM and analysed as in Fig. 1. *a*, Paper electrophoresis of *Penicillium* nuclease plus phosphatase digest; *b*, paper chromatography of enzyme-resistant, ^{3}H-labelled material from *a*; *c*, paper electrophoresis of nucleotide pyrophosphatase plus phosphatase digest of material in *b*. Marker compounds m^{7}GpppG^m and m^{7}GpppA^m were purified from *Penicillium* nuclease plus alkaline phosphatase digests of methylated mRNAs of reovirus[1] and cytoplasmic polyhedrosis virus[13], respectively.

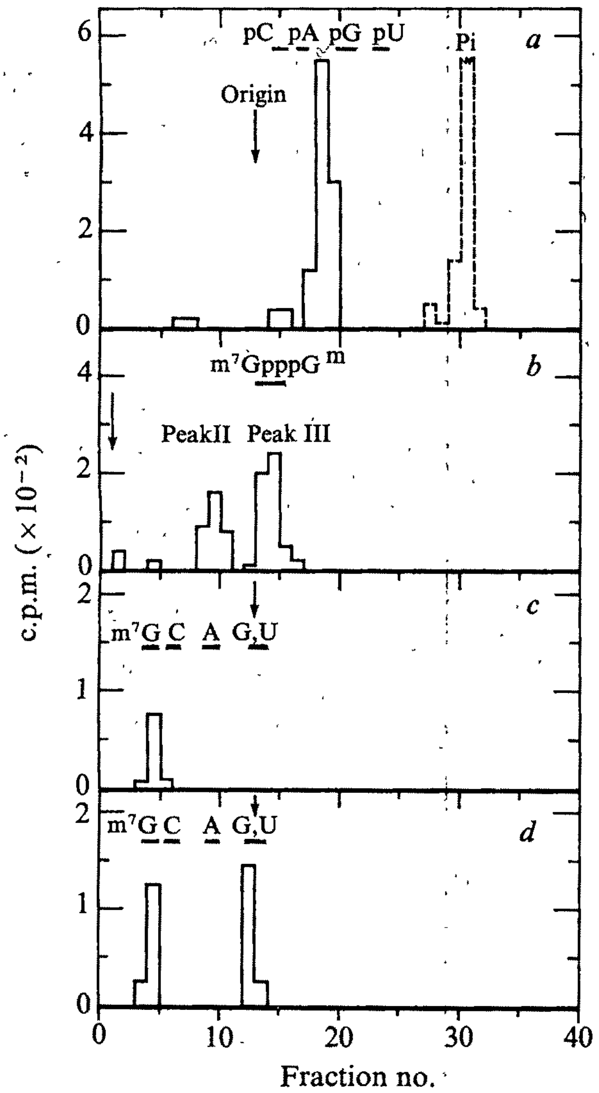

Fig. 3 Methylation of reovirus mRNA 5′ termini by L cell extract. Reovirus mRNA (10 μg) made in the presence of α-^{32}P-CTP and 10 μM SAH[3,6] was incubated under conditions of protein synthesis for 20 min in L cell extract[10] with methyl-^{3}H-SAM (3.4 μM, 7.3 Ci mmol^{-1}). The RNA was isolated and analysed as in Fig. 1. *a*, Paper electrophoresis of *Penicillium* nuclease and alkaline phosphatase digest; *b*, paper chromatography of enzyme-resistant, ^{3}H-labelled material in *a*; *c*, electrophoresis of peak II material after digestion with nucleotide pyrophosphatase and phosphatase; *d*, peak III material analysed as in *c*.

but by paper chromatography two components could be resolved (Fig. 3*b*). The faster component (peak III) migrated with m^{7}GpppG^{m} and the second component (peak II) migrated more slowly, as observed for m^{7}GpppG (peak I, Fig. 1*b*). Incubation with nucleotide pyrophosphatase plus alkaline phosphatase converted all the radioactivity in peak II to m^{7}G (Fig. 3*c*). By contrast, enzyme treatment of peak III yielded ^{3}H-labelled m^{7}G and an equal amount of radioactivity migrating in the position of G (Fig. 3*d*), which was identified as 2′-O-mG by paper chromatography. Therefore, cell-free extracts of both wheat germ and L cells contain enzyme activities that specifically methylate the N^{7} position of the 5′-terminal guanosine. L cell extracts, however, can also methylate the 2′-OH of the 5′ penultimate guanosine in reovirus mRNAs.

Dependence of translation on 5′-m^{7}G

Translation of reovirus and VSV mRNA by wheat germ extracts has been shown to depend on methylation of the mRNA (ref. 5). From the results shown in Figs 1 and 2, it is likely that N^{7} methylation of the 5′-terminal guanosine of viral mRNA is sufficient to satisfy the requirement for translation. Since the m^{7}G is in pyrophosphate linkage through its 5′-OH to the adjacent nucleotide[1], it contains free 2′, 3′-hydroxyl groups and can be removed after periodate oxidation by β elimination with aniline[7,11]. The effect of the removal of m^{7}G on reovirus mRNA activity was tested as follows. Reovirus mRNA was synthesised *in vitro* in the presence of SAM. It contained a mixture of molecules with 5′-terminal m^{7}GpppG^{m} (75%) and ppG (25%) (our unpublished results). After sequential treatment of the mRNA with periodate and aniline[7,11], the extent of removal of the 5′-terminal m^{7}G was 87% as determined with ^{3}H-methyl-labelled mRNA synthesised and treated in parallel. Since the translation of methylated reovirus mRNA is unaffected by SAH[5], the relative messenger activities of β-eliminated and untreated mRNAs were compared in wheat germ extracts containing SAH to prevent methylation of the 5′-terminal guanosine during protein synthesis. As Fig. 4 shows, β-elimination of premethylated mRNA resulted in the loss of about 85% of the mRNA activity compared with removal of most of the 5′-terminal m^{7}G. This loss of activity was not caused by chemical degradation of the RNA since the sedimentation profiles of the β-eliminated and untreated mRNAs in glycerol gradients were identical and included the l, m and s classes of mRNA[3].

Furthermore, the messenger activity of the β-eliminated RNA which consists of a mixture of molecules with 5′ termini of the types: (*a*) pppG^{m} (87%×75% = 66% of the total), (*b*) m^{7}GpppG^{m} (9%) and (*c*) ppG (25%), was partially restored when SAM was included in the wheat germ extracts (Fig. 4). The results indicate that chemical treatment did not irreversibly inactivate the mRNA. If, as suggested by these results, m^{7}G is

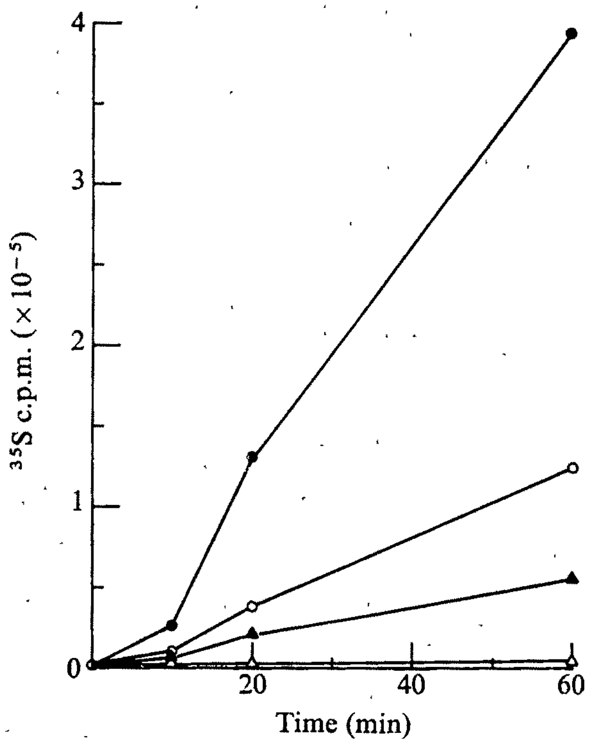

Fig. 4 Effect of removal of 5′-terminal m^{7}G on the ability of reovirus mRNA to stimulate protein synthesis. Methylated mRNA was synthesised *in vitro* with purified reovirus[3]. A sample of this RNA was oxidised with 10 mM potassium periodate, and the 5′-terminal m^{7}G was removed by incubation for 2 h at room temperature with 0.33 M aniline[11,12]. Equal amounts of untreated and treated RNA were used to programme polypeptide synthesis in wheat germ cell-free extracts as described[5]. Incorporation of ^{35}S-methionine into acid-precipitable material was determined. Untreated mRNA in the presence of 160 μM SAH (●); β-eliminated mRNA with 160 μM SAH (▲) or 2 μM SAM (○); and no added mRNA (△).

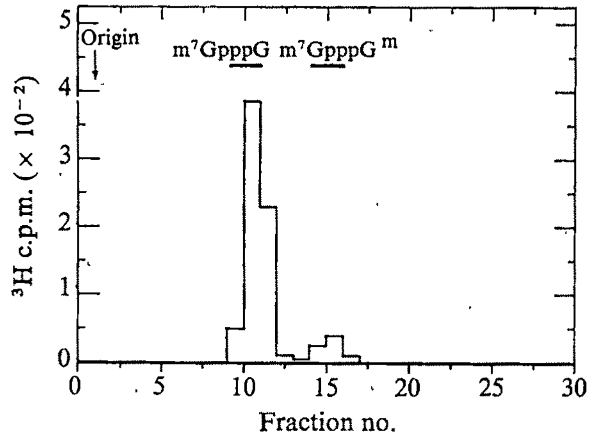

Fig. 5 5′-Terminal structure of β-eliminated reovirus mRNA after methylation by wheat germ extract. β-Eliminated reovirus mRNA was incubated for 20 min in conditions of protein synthesis in wheat germ extract with methyl-^{3}H-SAM (2 μM, 7.3 Ci mmol^{-1})[8]. The methylated RNA was isolated by phenol extraction and glycerol gradient centrifugation as in Fig. 1. After digestion with *Penicillium* nuclease and alkaline phosphatase, the enzyme-resistant ^{3}H-labelled material was analysed by paper chromatography[1]. The marker compounds were purified by electrophoresis of *Penicillium* nuclease plus phosphatase digests of reovirus mRNA methylated during transcription by virions (m^7GpppG^m) or during protein synthesis by wheat germ extract (m^7GpppG).

essential for translation of viral mRNA, restoration of the messenger activity of β-eliminated mRNA should be accompanied by the formation of new 5′-terminal m^7G. To test this possibility, treated mRNA was incubated with the wheat germ extract in the presence of ^{3}H-methyl-SAM in conditions used for protein synthesis. Radioactivity was incorporated into the RNA, and analysis by the procedures described in Fig. 1*a* revealed that all the ^{3}H was present in 5′-terminal structures. To determine which types of 5′ termini are substrates for methylation by the wheat germ extract, the ^{3}H-labelled mRNA was isolated from the extract after protein synthesis, digested with *Penicillium* nuclease and alkaline phosphatase and analysed by paper chromatography (Fig. 5). About 95% of the radioactivity migrated with m^7GpppG. The 5′-terminal material was further characterised as the monomethyl structure by nucleotide pyrophosphatase and phosphatase digestion followed by electrophoresis as in Fig. 3. The remaining radioactivity (5%) migrated in the position of m^7GpppG^m, indicating that only a small fraction of the predominant type of mRNA molecules, that is those with 5′-terminal pppG^m, can be methylated and blocked by the wheat germ extract. The results demonstrate that the recovery of messenger activity of β-eliminated RNA is paralleled by the formation of new 5′ termini containing m^7GpppG from molecules with 5′-terminal ppG. Since molecules containing 5′-terminal ppG comprise only one-fourth of the total mRNA, this finding is consistent with the incomplete restoration of the activity of β-eliminated mRNA.

5′-m^7G in reticulocyte mRNA

Globin mRNA, like reovirus RNA[12], is resistant to 5′-terminal labelling by the polynucleotide kinase procedure (R. Williamson, unpublished) suggesting that this cellular mRNA has blocked 5′ ends similar to those found in viral mRNAs. To test for the presence of 5′-terminal m^7G, rabbit reticulocyte mRNA was oxidised, reduced with ^{3}H-borohydride and analysed as in Fig. 1*a*. In addition to the 3′-terminal adenosine (520 c.p.m.), a peak of radioactivity (350 c.p.m.) was obtained in the position of presumptive 5′ termini (data not shown). Digestion of this 5′-terminal material with nucleotide pyrophosphatase and phosphatase converted all the radioactivity to the trialcohol derivative of m^7G (Fig. 6*a*). The results indicate that reticulocyte mRNA contains 5′-terminal m^7G in 5′ pyrophosphate linkage, that is with free 2′, 3′-hydroxyls. 5′-Pyrophosphate structures of this type are sensitive to β-elimination as shown for reovirus RNA[7,12]. If 5′-terminal m^7G is also required for translation of cellular mRNAs, its removal from reticulocyte mRNA by β-elimination should be accompanied by a loss of polypeptide synthesis in cell-free protein synthesising systems programmed by the treated mRNA. As Fig. 6*b* shows, after β-elimination, reticulocyte mRNA lost 80% of its capacity for stimulating protein synthesis. Treated and untreated mRNA coded almost entirely for a polypeptide which comigrated with globin during sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis and its synthesis was reduced by80% following β-elimination of the mRNA.

A unique 5′-terminal structure of the type, m^7G(5′)ppp(5′)N^m has been found in various viral and cellular mRNAs including those of cytoplasmic polyhedrosis virus[13], reovirus[1,7], vaccinia[14,15], VSV[2], SV40[16], adenovirus (Y.F., A.J.S. and J. E. Darnell, unpublished), mouse L cells (Y.F., A.J. LaFiandra and A.J.S., unpublished results), monkey BSC-1 cells[16] and HeLa cells[17]. A common feature of these mRNAs is the presence of 5′terminal m^7G. The nature of the adjacent 2′-O-methylated nucleotides apparently varies. In addition, a series of low molecular weight RNAs from Novikoff hepatoma

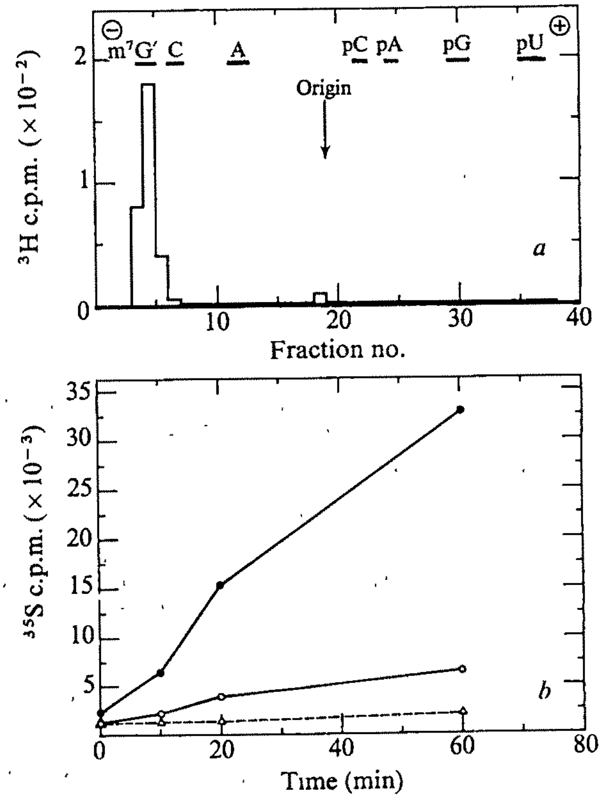

Fig. 6 5′-Terminal m^7G in reticulocyte mRNA and loss of translational activity after removal of m^7G by β-elimination. Reticulocyte mRNA was purified from cell lysates by phenol extraction and two rounds of binding to oligo(dT)-cellulose[21]. Aliquots of the eluted mRNA were used for labelling with ^{3}H-borohydride and for translation before and after β-elimination. *a*, mRNA was oxidised with 10 mM potassium periodate, reduced with potassium borohydride-^{3}H (10 mCi, 3.3 Ci mmol^{-1}), and digested with *Penicillium* nuclease and alkaline phosphatase. The presumptive 5′-terminal material was purified by paper electrophoresis, eluted, digested with nucleotide pyrophosphatase and phosphatase and analysed by paper electrophoresis. *b*, Equal amounts of mRNA (0.7 μg per 12.5 μl reaction mixture) were used to stimulate protein synthesis in wheat germ extracts before and after β-elimination as in Fig 4. Untreated mRNA in the presence of 160 μM SAH (●); β-eliminated mRNA in the presence of 160 μM SAH (○); no added mRNA (△).

cell nuclei have been found to contain 5′-terminal $m_3^{2,2,7}G(5')pp(5')N^mN^mN$, but their biological function has not been established[18]. Our results suggest that in addition to a possible role in mRNA processing[19], the 5′-terminal m^{7}G in mRNA is essential for translation. Unmethylated VSV and reovirus mRNAs, which are inactive in a wheat germ protein-synthesising system in the presence of SAH, become active when methylated[5]. Methylation occurs specifically in the 5′-terminal guanosine at the N^7 position. Removal of the m^{7}G by β-elimination of methylated mRNA results in a concomitant loss in the ability to stimulate protein synthesis. The presence of a 5′-terminal 2′-O-methylated nucleotide is not required for mRNA functions since the β-eliminated mRNA which contains 5′-terminal pppG^m is inactive and molecules containing m^{7}GpppG or m^{7}GpppA are active in protein synthesis. Reovirus mRNA synthesised in the presence of SAH contains 25% of the molecules with 5′-terminal GpppG (our unpublished results), and VSV mRNA made in the absence of SAM contains 5′-terminal GpppA (ref. 8). In each case, the mRNAs with blocked but unmethylated 5′ ends are inactive and become functional only after conversion to m^{7}GpppN. Reticulocyte RNA contains 5′-terminal m^{7}G and its removal by β-elimination results in the loss of its ability to stimulate polypeptide synthesis *in vitro*. It will be interesting to determine if 5′-terminal m^{7}G is a structural feature of all eukaryotic mRNAs that is required for a specific step in protein synthesis that is, ribosome binding.

We thank A. LaFiandra and M. Morgan for assistance. VSV mRNA was provided by A. K. Banerjee and D. Rhodes, and reticulocyte lysate was a gift from R. Gesteland.

Novel initiation of RNA synthesis *in vitro* by vesicular stomatitis virus

Gordon Abraham, Dennis P. Rhodes & Amiya K. Banerjee

Roche Institute of Molecular Biology, Nutley, New Jersey 07110

The mRNA synthesised in vitro *by the virion-associated RNA polymerase of vesicular stomatitis virus contains the novel 5′-terminal structure G(5′)ppp(5′)Ap. . . . may be an intermediate in the formation of the 5′-termini of eukaryotic mRNAs.*

ALL messenger RNAs isolated from prokaryotes and from bacteriophages seem to be initiated by triphosphates at their 5′-termini[1-4]. In contrast, the 5′-terminal structures of natural eukaryotic mRNAs are believed to be different since they are resistant to phosphorylation by polynucleotide kinase after prior treatment with alkaline phosphatase[5]. The mRNAs synthesised *in vitro* by the RNA polymerases associated with the viral cores of several animal viruses including vaccinia virus[6], reovirus[7], vesicular stomatitis virus (VSV)[8] and silkworm cytoplasmic polyhedrosis virus (SCPV)[9], however, have either di- or triphosphates at their 5′-termini. Each of these viruses has been shown to possess an RNA methylase activity which transfers methyl groups from S-adenosyl-methionine (SAM) to the 5′-termini of mRNAs during their synthesis *in vitro*[10-13]. Furthermore, these methylated mRNAs all contain at their 5′-termini a blocked structure consisting of 7-methylguanosine linked by a pyrophosphate bridge to a 2′-O-methylated purine, having the general form $m^7G(5')ppp(5')Pup^m$. . . (refs 14–16). In the case of VSV the 5′-terminal structure is $m^7G(5')ppp(5')Ap^m$. . .[17].

During investigation of the mechanism of formation of this unusual structure, we discovered that in certain conditions, the virion-associated RNA polymerase of VSV synthesised RNA *in vitro* which terminated with a new type of structure, which was blocked but not methylated. This type of structure may be an intermediate in the formation of the 5′-termini of eukaryotic mRNAs.

Blocked 5′-terminal phosphates

The virion-associated RNA polymerase of VSV can be activated by non-ionic detergents to synthesise RNA products *in vitro* which are complementary to the genome RNA[18], contain poly(A) sequences at their 3′-termini[19] and are biologically active as messenger RNAs in a cell-free protein synthesising system[20]. Using Triton-disrupted VSV, we observed previously[12] that β,γ-^{32}P GTP was incorporated into the 5′-termini of the product RNA, but not β,γ-^{32}P ATP. This was unexpected since Roy and Bishop[8], using core particles derived from VSV by a polyethylene glycol-dextran phase separation procedure, found that most of the product RNA molecules contained 5′-pppA. VSV mRNA was synthesised *in vitro* using β,γ-^{32}P GTP as the labelled substrate, purified, and the 12-18S mRNA[21] was recovered as described in the legend for Fig. 1. After digestion with RNAase T$_2$ (which degrades RNA to 3′-nucleotides), the products were analysed by DEAE-cellulose chromatography as shown in Fig. 1. The major peak of radioactivity eluted at the position of tetranucleotides (−5 charge) and a minor peak (10–15%) at a slightly higher salt concentration. The presumptive 5′-terminal oligonucleotide contained in the major peak migrated to a position between the two mononucleotide markers, pG and pU, when analysed by paper electrophoresis (Fig. 2*a*). When digested with nuclease P$_1$ from *Penicillium citrinum*[22] (which degrades RNA to 5′-nucleotides) and alkaline phosphatase, all the ^{32}P-radioactivity was retained in a product

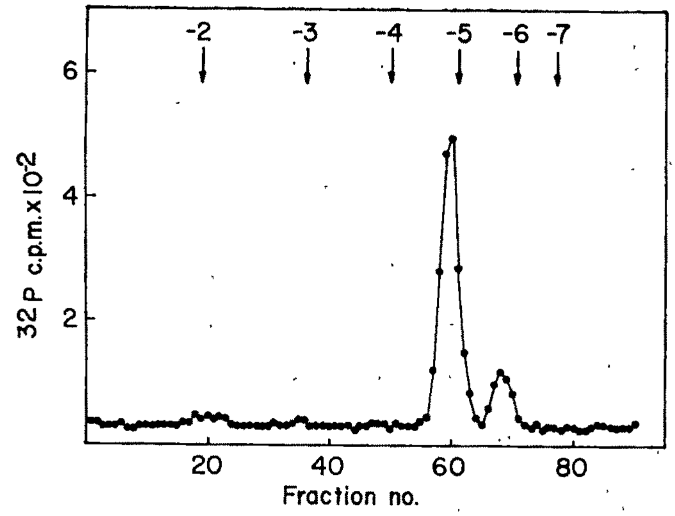

Fig. 1 DEAE-cellulose chromatography of the products of ribonuclease T_2 digestion of mRNA synthesised in the presence of β,γ-^{32}P-GTP. VSV mRNA was synthesised *in vitro* in an incubation mixture (0.4 ml) which contained 0.1 M NaCl, 0.05 M Tris-HCl (*p*H 8.0), 5 mM $MgCl_2$, 4 mM dithiothreitol, 1 mM ATP and CTP, 0.1 mM GTP and UTP, 63 μCi β,γ-^{32}P-GTP (3.7 Ci mmol^{-1}), 0.05% Triton N101, and 80–100 μg purified VSV. After incubation for 2 h at 30 °C, the reaction was terminated by addition of sodium dodecyl sulphate (SDS) to 0.5%. The product RNA was extracted with phenol, purified by Sephadex G-100 chromatography, and analysed by sedimentation for 17 h at 45,000*g* in a 15–30% (w/v) linear sucrose gradient containing 0.5% SDS[12]. The VSV mRNA species sedimenting between 12S and 18S (ref. 21) were pooled and precipitated with ethanol. The recovered RNA was digested with 2.5 U ribonuclease T_2 (Sankyo Co.) in 10 mM sodium acetate (*p*H 4.5) for 5 h at 37 °C. The products were eluted from a DEAE-cellulose column with a linear gradient of NaCl[23] and the radioactivity in each fraction was determined as Cherenkov radiation. Arrows indicate the elution positions of marker oligonucleotides expressed as their net negative charges.

which shifted to a position between the markers pA and pG (Fig. 2*b*). This result was consistent with the removal of an unlabelled phosphate group from the 3′-end of the oligonucleotide and showed that the ^{32}P-radioactivity derived from β,γ-^{32}P-GTP was completely protected from the action of alkaline phosphatase. On the other hand, the ^{32}P-radioactivity was entirely released as Pi when the 5′-terminal oligonucleotide (−5 charge) was treated with nucleotide pyrophosphatase, indicating that a pyrophosphate bond existed at the 5′-termini of the RNA molecules, possibly as $G_{(ppp)}X_p$, or $X_{(ppp)}G_p$, where X is an unknown base. The minor oligonucleotide peak eluting at −6 charge (Fig. 1) behaved identically when treated with the enzymes described above, and is believed to be a 5′-terminal fragment resulting from incomplete digestion by RNase T_2 (data not shown).

Structure of blocked 5′-termini

VSV mRNA was synthesised *in vitro* using α-^{32}P-GTP as the labelled substrate, and purified. The labelled RNA was digested with RNase T_2, and the products were analysed by DEAE-cellulose chromatography. Most of the radioactivity eluted as mononucleotides (−2 charge) but a fraction (0.24%) of the radioactivity eluted as a single peak at −5 charge similar to that shown in Fig. 1 (data not shown). This 5′-terminal oligonucleotide(s) was analysed further by paper electrophoresis following various enzymatic digestions as shown in Fig. 3. When treated with both nuclease P_1 and alkaline phosphatase (Fig. 3*a*) the radioactivity appeared as a single peak between pA and pG (compare Fig. 2*a*). When this material was treated with nucleotide pyrophosphatase, all the ^{32}P-radioactivity now comigrated with the pG marker (Fig. 3*b*). When alkaline phosphatase was added with nucleotide pyrophosphatase, all the radioactivity migrated as Pi (Fig. 3*c*). These results, together with that shown in Fig. 2, showed that the α- and β-phosphates of GTP were incorporated into the blocked structure, as $Gp^{\alpha}p^{\beta}$–pXp or Xp–$p^{\beta}p^{\alpha}$Gp.

Attempts to label the 5′-terminal oligonucleotide with α-^{32}P-CTP or α-^{32}P-UTP were unsuccessful. However, when α-^{32}P-ATP was used as the labelled substrate, a 5′-terminal fragment (−5 charge) similar to that obtained using α-^{32}P-GTP-labelled products, was recovered as described above. In contrast to the products labelled with α-^{32}P-GTP (Fig. 3*a*), 50% of the ^{32}P-radioactivity was released as Pi after digestion with nuclease Pi and alkaline phosphatase (Fig. 4*a*). This result showed that two phosphate groups from the α-position of ATP were incorporated into the −5 charged terminal fragment, and that one of them was 3′-terminal, being derived from ATP by nearest neighbour transfer. The other phosphate group was included in the blocked structure which migrated at the characteristic position between pA and pG (Fig. 4*a*). When the latter material was treated with nucleotide pyrophosphatase, all the ^{32}P-radioactivity comigrated with pA (Fig. 4*b*) and when treated with both nucleotide pyrophosphatase and alkaline phosphatase, all the radioactivity migrated as Pi (Fig. 4*c*). The pG and pA liberated by treatment of the putative 5′-dinucleotide with nucleotide pyrophosphatase (Figs 3*b* and 4*b*) were further confirmed to be authentic unmethylated pG and pA by paper chromatographic analyses

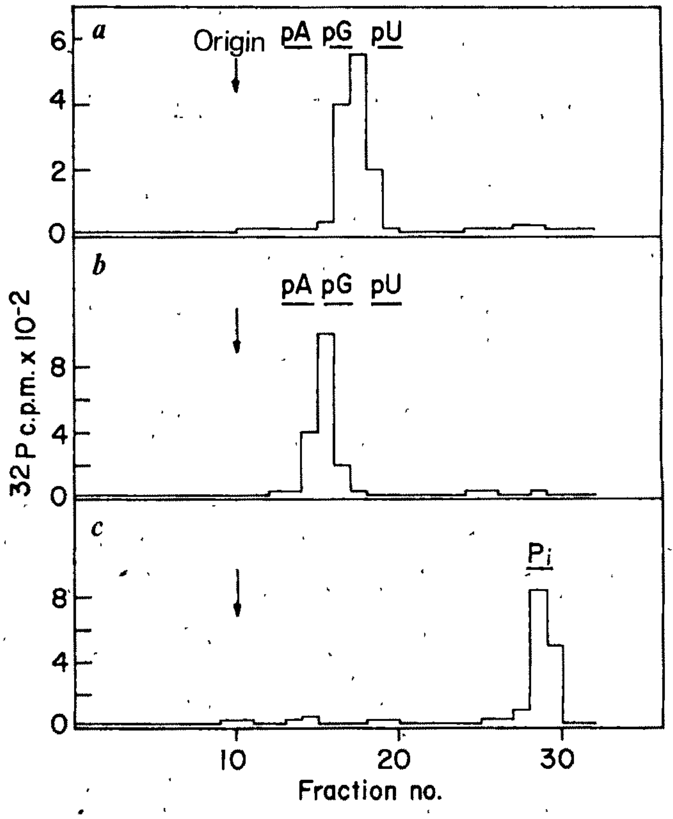

Fig. 2 Paper electrophoretic analyses of the products of enzymatic digestions of labelled RNA. The fractions containing the major peak of radioactivity eluting at −5 charge in Fig. 1 were pooled and desalted by dialysis. *a*, One portion was analysed directly by paper electrophoresis at *p*H 3.5[15]; *b*, a second portion was digested with nuclease Pi (a gift from Dr Kuninaka, Yamasa Co., Japan; 200 μg ml^{-1} in 10 mM sodium acetate, *p*H 6.0) for 30 min at 37 °C, followed by digestion with bacterial alkaline phosphatase (Worthington; 20 U ml^{-1} in 20 mM Tris-HCl, *p*H 8.0) for 30 min at 37 °C before analysis; *c*, a third portion was digested with nucleotide pyrophosphatase (Sigma; 0.05 U ml^{-1} in 20 mM Tris-HCl, *p*H 7.5, and 1 mM $MgCl_2$) for 15 min at 37 °C before analysis. Marker 5′-mononucleotides were included with the samples and their positions after electrophoresis were located by ultraviolet absorption. The paper was cut into 1-cm strips and the radioactivity in each was determined by scintillation counting.

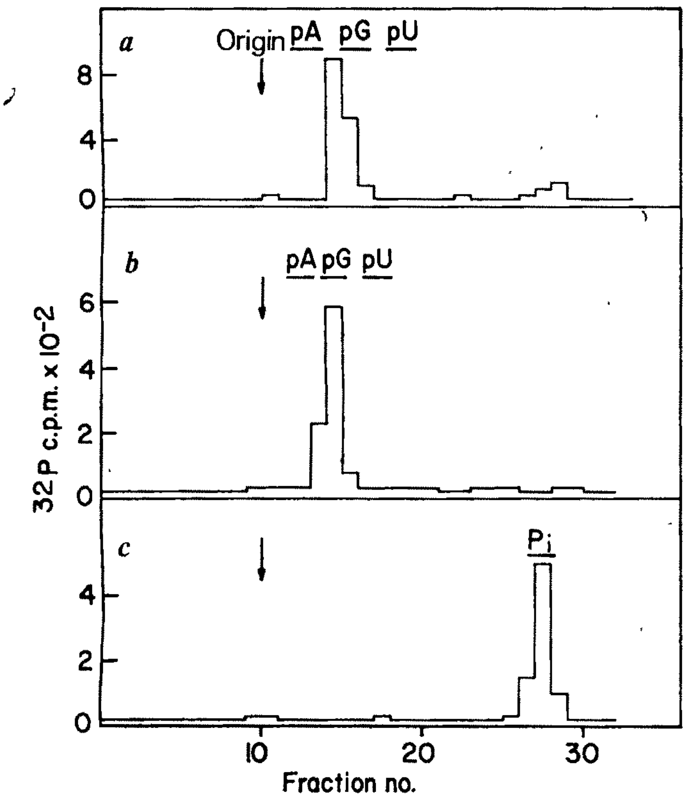

Fig. 3 Paper electrophoretic analyses of the products of enzymatic digestions of RNA labelled with α-^{32}P-GTP. VSV mRNA was synthesised and purified as described in the legend for Fig. 1 except that 50 μCi α-^{32}P GTP (18.5 Ci mmol^{-1}) was used as the labelled substrate. After ribonuclease T_2 digestion of the 12-18S mRNAs, the radioactive material which eluted from DEAE-cellulose at −5 charge (compare Fig. 1) was dialysed and digested with nuclease P_1 followed by alkaline phosphatase as described previously. *a*, This material was analysed directly by paper electrophoresis; *b*, the radioactive material from panel (*a*) was eluted from the paper, digested with nucleotide pyrophosphatase and a portion analysed directly; *c*, a second portion was digested with alkaline phosphatase before analysis.

(data not shown). From these results, the 5′-terminal structure of 12-18S VSV mRNA can be depicted as Gp$^{\alpha}$p$^{\beta}$–p$^{\alpha}$Ap$^{\alpha}$A . . . or Ap$^{\alpha}$–p$^{\beta}$p$^{\alpha}$Gp$^{\alpha}$A . . . .

Identity and orientation of blocking base

The appearance of the α-phosphates of both ATP and GTP in the blocked structure suggested that a 5′-5′ linkage was present, possibly as G(5′)ppp(5′)Ap . . . . If this structure does exist at the 5′-end of mRNA, the blocking base will contain free 2′- and 3′-hydroxyl groups and so will be susceptible to removal by periodate oxidation followed by treatment with aniline[24]. Accordingly, VSV mRNA synthesised using β,γ-^{32}P-GTP as the labelled substrate was purified and treated with potassium periodate followed by aniline. The resulting β-eliminated RNA was precipitated, digested with nuclease Pi, and analysed by paper electrophoresis (Fig. 5*a*). Approximately 65% of the ^{32}P-radioactivity comigrated with authentic ^{3}H-ATP marker, but not with GTP, which migrated 1 cm further. The remaining ^{32}P-radioactivity migrated as Pi and presumably resulted from trace amounts of contaminating phosphatases. The radioactive material that comigrated with ATP was eluted from the paper and digested with alkaline phosphatase before electrophoresis (Fig. 5*b*). All the ^{32}P-radioactivity was released as Pi, which indicated that the blocking group had been removed by β-elimination. As expected, the internal ^{3}H-ATP marker was converted to ^{3}H-adenosine by alkaline phosphatase. From these results we conclude that the 5′-terminal structure of the 12S–18S VSV mRNA synthesised *in vitro* is G(5′)ppp(5′)Ap . . . .

Possible intermediate in mRNA biogenesis

The results documented above illustrate that the virion-associated RNA polymerase of VSV synthesises mRNAs *in vitro* which contain a special type of modification at their 5′-termini. When RNA is synthesised *in vitro* using Triton-disrupted VSV, we observed: (1) no mRNA species are made which terminate with conventional di- or triphosphates, indicating that the blocking reaction, which renders 5′-terminal phosphates of RNA resistant to alkaline phosphatase, is complete; (2) in the absence of exogenous SAM no methylated nucleotides are detected at the 5′-termini, indicating that there is no endogenous methyl donor present in purified VSV and that addition of the blocking group does not require methylation; (3) when SAM is available during RNA synthesis the 5′-termini of all of the mRNA molecules are blocked and methylated[17]. Thus, it seems that in the VSV system there are two distinct enzymatic processes involved in the modification of the 5′-termini of the product mRNAs. An unmethylated, blocked terminal structure is formed first which then presumably is the substrate for subsequent methylation.

Using VSV ribonucleoprotein cores, prepared by a polyethylene glycol–dextran phase separation procedure, Roy and Bishop[8] reported that the RNA products synthesised *in vitro* were initiated with pppA . . . and pppG . . . . It seems likely that this fractionation procedure may have either removed or inactivated the blocking activity. Thus, it may be possible to isolate from VSV a separate enzyme which catalyses the blocking reaction. It has been reported that reovirus[7], vaccinia virus[6] and SCPV[9] synthesise RNA *in vitro* containing di- or

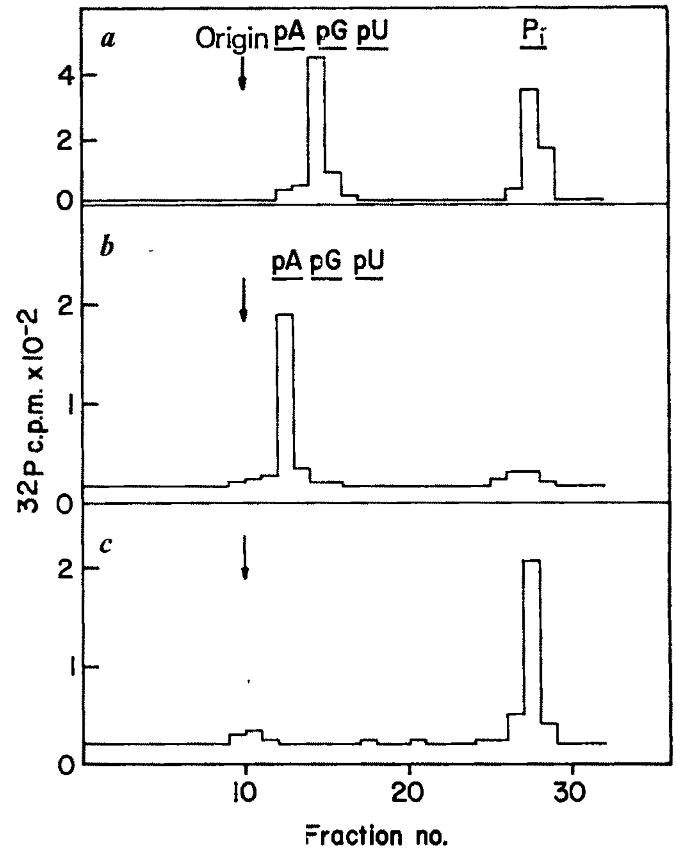

Fig. 4 Paper electrophoretic analyses of the products of enzymatic digestion of RNA labelled with α-^{32}P ATP. Experimental procedures were identical to those described in the legend for Fig. 3 except that 42 μCi α-^{32}P-ATP (15.7 Ci mmol^{-1}) was used as the labelled substrate. *a*, Analysis of the products after digestion with nuclease Pi followed by alkaline phosphatase; *b*, the radioactive material migrating between pA and pG in panel (*a*) digested with nucleotide pyrophosphatase; *c*, the same radioactive material from panel (*a*) digested with nucleotide pyrophosphatase followed by alkaline phosphatase.

triphosphates at their 5′-termini. In the presence of SAM, however, these same viruses can synthesise RNA which is both blocked and methylated[10,11,13]. It will be interesting to see whether unmethylated, blocked mRNA intermediates are synthesised *in vitro* by these viruses in suitable conditions. In fact, unpublished observations (S. Muthukrishnan and A. J. Shatkin, personal comminication) with reovirus indicate that approximately 20% of the mRNA molecules synthesised *in vitro* contain unmethylated blocked 5′-termini.

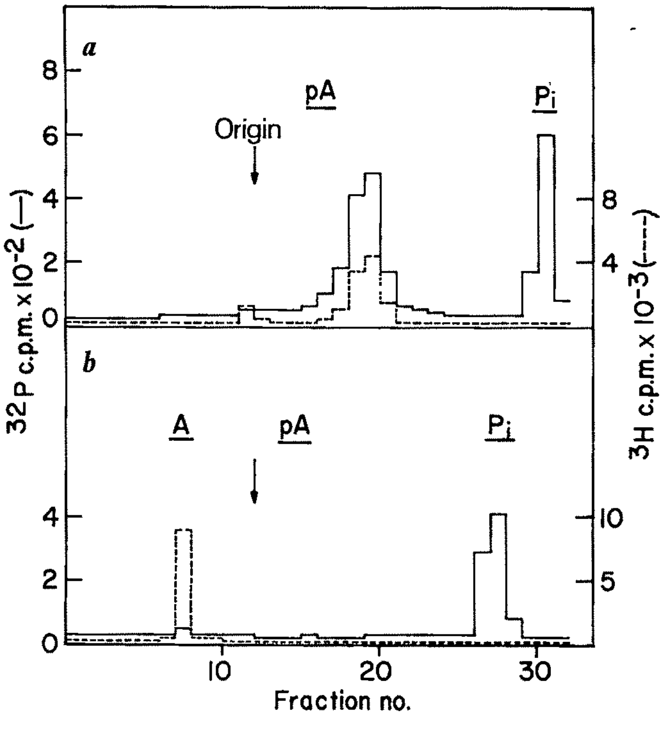

Fig. 5 Paper electrophoretic analyses of RNA products following β-elimination of β,γ-^{32}P-labelled VSV mRNA. VSV mRNA was synthesised and purified as described in the legend for Fig. 1. The 12S-18S mRNA species were oxidised with potassium periodate followed by treatment with aniline according to the method of Hunt[24], and the treated RNA was digested with nuclease Pi for 3 h. *a*, The products of this digestion were mixed with an authentic sample of ^{3}H-ATP and analysed by paper electrophoresis; *b*, the radioactive material which co-migrated with ATP in panel (*a*) was eluted from the paper and digested with alkaline phosphatase before electrophoresis.

Recent reports have indicated that eukaryotic mRNAs are methylated[25,26]. Moreover, methylated and blocked 5′-terminal structures of the form $m^7G(5')ppp(5')X^m$ are present in both HeLa and mouse L-cell mRNAs (Y. Furuichi and A. J. Shatkin, personal communication). Similarly, we have recently shown that the viral mRNAs isolated from VSV-infected cells also contain the same type of blocked and methylated structures[27].

These observations suggest strongly that the terminal modifications of mRNAs are biologically important events. The blocked but unmethylated 5′-terminal structure observed in the VSV system may be a general type of intermediate in the biosynthesis of eukaryotic mRNAs.

Origin of broad interstellar feature at 1.6 μm^{-1}

DIFFUSE interstellar absorption bands at 4,430, 4,760, 4,890 and 6,180 Å have been assigned to crystal-field transitions of octahedrally and tetrahedrally bonded ferric ions in an iron oxide[1-3]. The optical absorption spectra of terrestrial iron bearing minerals[4-6] often comprise, in addition to the crystal-field bands, a broad absorption (half-width 3,000 cm^{-1}) in the range 14,000–18,500 cm^{-1} (715–540 nm) marking $Fe^{2+}3dt_2 \rightarrow Fe^{3+}3dt_2$ intervalence charge transfer, the cations being located at the centres of adjacent edge-sharing octahedra. Here, I suggest that a discontinuity at ~ 1.6 μm^{-1}, which I see as a minor feature on the mean extinction curve[7] for several reddened stars, represents $Fe^{2+} \rightarrow Fe^{3+}$ charge transfer absorption in interstellar grains. A shallow emission feature observed at ~ 1.8 μm^{-1} in the reddening curve for another group of stars has been interpreted[8] as a dip lying between two absorptions centred at ~ 1.5 and ~ 2.4 μm^{-1}.

Extinction coefficients (ε) for $Fe^{2+} \rightarrow Fe^{3+}$ bands in silicates[4] are ~ 150 l mol^{-1} cm^{-1}, where ε is calculated from the band absorbance divided by the product of the specimen thickness (in cm) and the cation pair concentration (in mol l^{-1}). This value of ε is probably valid for oxides. The intense absorption of light by magnetite, Fe_3O_4 arises from a combination of $Fe^{2+} \rightarrow Fe^{3+}$ processes and crystal-field transitions ($\varepsilon \sim 500$; $f \sim 0.001$) in magnetically coupled ferric ions[9,10]. In magnetite[11], the 16-fold octahedral positions are occupied by equal concentrations of ferrous and ferric ions, and the 8-fold tetrahedral positions are occupied by ferric ions. Each octahedrally bonded ferrous ion shares four octahedral edges with adjacent Fe^{3+} centred octahedra. The Fe^{2+} concentration is 22.5 M, so the effective concentration of ferrous–ferric pairs is 90 M. The estimated absorption of the 1.6 μm^{-1} feature is 0.1 mag kpc^{-1}, corresponding to a thickness of magnetite along the line of sight of 0.03 μm. For a 1 cm^2 cross section of Fe_3O_4 over 1 kpc, the average density of Fe_3O_4 in the interstellar medium is therefore 1.6×10^{-26} g cm^{-3}. The iron density is then 1.2×10^{-26} g cm^{-3}, which is close to the currently accepted value [1] of 0.7×10^{-26} g cm^{-3}. This calculation shows that an oxide such as Fe$_3$O$_4$, with ferrous and ferric ions in adjacent edge-sharing octahedra, could be a component of interstellar dust.

The substitution of Ti^{4+} ions[12] into octahedral positions in magnetite will cause Fe$^{2+} \rightarrow$ Ti^{4+} charge transfer. This process is marked in terrestrial silicates by a broad absorption (half-width 5,000 cm^{-1}) centred in the 21,000–23,000 cm^{-1} (476–435 nm) region of the spectrum [6,13], with $\varepsilon \sim 10^4$ l mol^{-1} cm^{-1}. The Fe–Ti cosmic abundance ratio[14] is 250:1 so on a purely statistical basis the Fe^{3+}–Ti^{4+} ratio in octahedral positions in titaniferous magnetite is 80:1. The ε-values for the two processes suggest that if the Fe$^{2+} \rightarrow$ Fe^{3+} process is observable then the Fe$^{2+} \rightarrow$ Ti^{4+}, process could also be seen and it is possible that the latter process may be responsible for absorption in the region of the knee[15,16] in the extinction curve at ~ 430 nm.

I thank Professor N. C. Wickramasinghe and members of his staff for discussions.

Absorption of soft X rays by material within Gould's Belt

EARLY surveys of the soft X-ray diffuse background revealed an overall decrease of ~250 eV intensity from the galactic pole to the galactic plane[1-5]. The effect was attributed to absorption by interstellar gas and it was widely accepted that a substantial fraction of the flux originated from beyond the galactic disk. But the detection of emission from the plane of the Galaxy[2,3] (unit optical depth ~200 pc) and from the vicinity of a radio continuum feature, the North Polar Spur[6,7], demonstrated that at least part of the flux is galactic in origin. Recent surveys[8,9] provide greater sensitivity and reliability. The ~250 eV results have been combined in Fig. 1. From these data it has been shown that several regions of enhanced emission are associated with radio continuum or Hα features, and that there is no simple quantitative relationship between the soft X-ray intensity and 21-cm values of neutral hydrogen column density. It has been concluded on this basis that most if not all of the flux is generated within the Galaxy (refs 8, 9 and A. N. Bunner, unpublished). Since stellar sources or diffuse non-thermal processes cannot easily account for the observed intensity[8,10], thermal bremsstrahlung from a hot gas is now accepted as the most probable source mechanism. The discovery of a shallow OVI absorption line in the spectra of many nearby stars supports this hypothesis[11-13].

In spite of the lack of quantitative correspondence between the ~250 eV flux and regions of low HI column density, the Wisconsin workers note that enhancements are often observed where the neutral gas is lacking[8]. In addition the data of Fig. 1 exhibit a gross trend to smaller intensities at low galactic latitudes in agreement with the earlier surveys. If these effects are caused, at least in part, by interstellar absorption, there should be a general anti-correlation of soft X-ray intensity with material within one optical depth of the Sun. For 250-eV X rays this implies a correspondence with interstellar gas closer than ~200 pc.

The brighter stars visible to the naked eye and nearby reflection nebulae form a localised subsystem of the Galaxy inclined at ~20° to the galactic plane[14-16], which can also be detected by 21 cm observations of the local neutral hydrogen gas[17,18]. The best fit hydrogen equator[18] (Fig. 2) deviates by less than 4° from the original Gould's Belt. A comparison of Figs 1 and 2 shows that in the areas surveyed so far there is strong evidence for soft X-ray absorption by the local interstellar gas. The regions of low (~250 eV) intensity follow the curve of the local hydrogen equator and cover parts of the Scorpius–Ophiuchus complex at positive latitudes ($l^{\rm II}$ ranges from 330° to 30°) and the Orion–Taurus bulge in the southern hemisphere ($150° < l^{\rm II} < 195°$). But the most remarkable correspondence occurs between regions of low ~250 eV intensity extending away from the local hydrogen belt and several of the low velocity neutral hydrogen ridges[19] (Fig. 2). Although in the present data the spatial coincidence is not always exact, the reality of absorption by features of this type has been demonstrated by the results of a recent latitude scan in the Virgo–Hydra region (unpublished data by C.G.R. and others).

The interpretation of the absorption data is not straightforward because of the complex nature of the distribution of

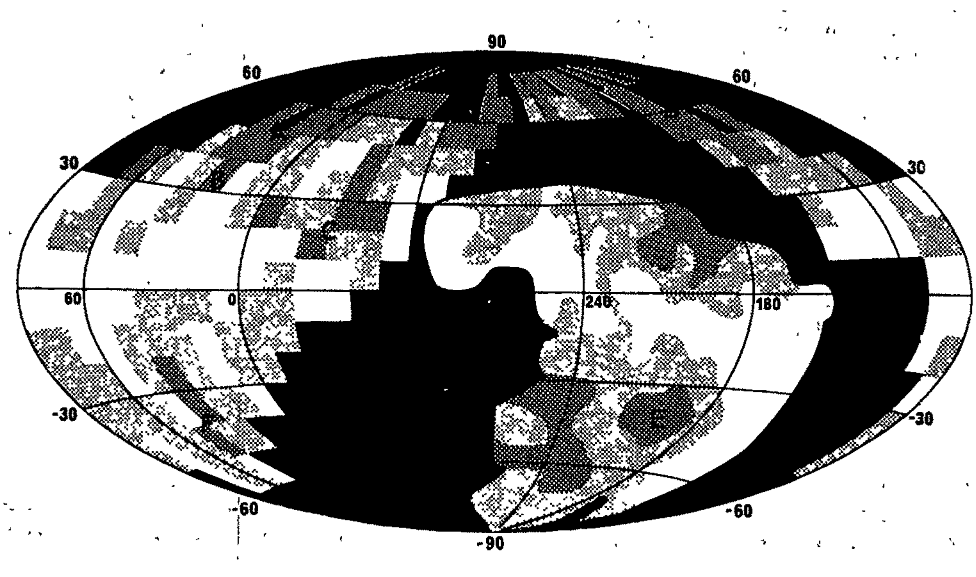

Fig. 1 The combined surveys of Williamson *et al.*[8] ($150° < l^{\rm II} < 290°$, $-90° < b^{\rm II} < 35°$) and De Korte[9] shown in galactic coordinates. Increased shading indicates increasing ~250 eV intensity except in the areas shown in black which have not been surveyed. The two intensity scales have been approximately normalised by comparing adjacent areas and by using the quoted brightness ranges. An area effected by scattered solar radiation has been removed from De Korte's survey[9] and the Vela–Puppis complex, visible in the original Wisconsin map[8], is not shown. Emission regions referred to in the text are labelled A–F.

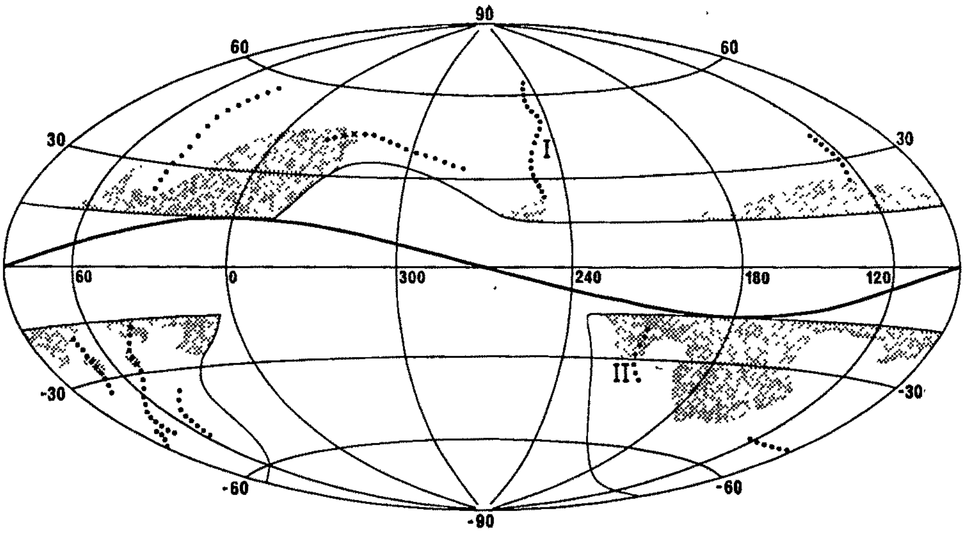

Fig. 2 The local neutral hydrogen equator taken from Goldstein and MacDonald[18] (thick line) with a representation of the extent of the major low velocity neutral hydrogen concentrations[19] (shaded) in the regions of sky for which data are available. The low velocity neutral hydrogen ridges of Fejes and Wesselius[19] are also shown (dots). The Sextans and Orion ridges are marked I and II respectively.

emitting and absorbing material. But the identification of enhancements A–F (Fig. 1) with radio continuum and Hα features [8,9,20,21] which are themselves closely interrelated[22] suggests that a combination of studies carried out over a wide range of wavelengths may result in a clearer understanding of the principal sources of emission. Large scale, ordered structures such as intersecting supernova shells[23] are of particular interest since the models of Spoelstra[24,25] show Radio Loops I and IV to intersect to form the first confirmed tunnel section. The radio continuum ridges and soft X-ray enhancements extending to high latitudes from region C in Fig. 1 may therefore be accounted for by emission from the tunnel wall.

Comparison of observed soft X-ray spectra with those derived from OVI results (which provide a value for the gas temperature) can provide distance estimates if values for the effective absorption cross section and average density of the intervening material are assumed. Approximate distances to several nearby emission regions can already be estimated from the data of Jenkins and Meloy[12].

Perhaps the most interesting absorption features shown in Fig. 1 are those associated with the neutral hydrogen ridges which often extend to intermediate or high latitudes. Since there is evidence that several of these ridges are associated with the radio loops[19], care must be taken when interpreting their modulation of the soft X-ray flux because they may merely separate regions of enhanced emission. The similarity of diffuse intensity on either side of the Sextans and Orion ridges (I and II in Fig. 2) suggests, however, that a genuine absorption effect is being observed. The 21-cm data and Brown and Gould coefficients[26] indicate that the additional gas path presented by each of these ridges is approximately one optical depth (63% modulation). So the observed modulations of ~20% (estimated from ref. 8) do not imply that a large fraction of the flux originates from beyond the ridges unless a significant unabsorbed local component of flux exists.

If it is assumed that the rather constant intensity observed in the plane of the local hydrogen gas represents such a component, the modulation of the remaining flux is ~50% and a substantial fraction of that flux would necessarily originate from beyond the ridges. Although the distances to the features are hard to estimate they probably extend as far as several hundred parsecs, and the existence of more distant regions of emission would imply an origin outside the galactic disk. It is difficult to see how such emission could be associated with a network of supernova tunnels unless some of these burst out of the neutral gas into a low density galactic halo. Although the present observations of the neutral hydrogen ridges can neither support nor rule out the existence of emission from beyond the galactic disk, the extended 250 eV enhancements at $l^{II} = 240°$, $-70° < b^{II} < -30°$ and in the Northern Hemisphere at $l^{II} \simeq 200°$ lie in the directions of the two deepest minima in the radio continuum sky[27] which coincide with regions of extremely low HI density. It may be difficult to account for these features by emission from within the Galaxy.

In conclusion it seems likely that the effects of soft X-ray absorption by material in Gould's Belt will contribute significantly to our understanding of the galactic sources of diffuse soft X-ray emission and may permit the uncertainty concerning the existence of a halo or extragalactic component of the flux to be resolved.

I thank Professor R. L. F. Boyd for encouragement and Drs J. L. Culhane and I. R. Tuohy for discussions.

Low frequency radio astronomy through an artificially created ionospheric window

THE ionosphere presents a nearly impenetrable barrier for ground-based decametric (3–30 MHz) radioastronomical observations, though a few valiant efforts have been made under special conditions to reach frequencies near 1 MHz (ref. 1).

To overcome this problem radio receivers can be placed on rockets and satellites[2-4]. There are, however, two basic problems with space radio observations. The first is the ambient plasma of the ionosphere, which at low frequencies interferes with the normal functioning of the antenna. The second is the very poor angular resolution available because the antenna rods used with these space vehicles are in general much shorter than the observing wavelength ($\lambda = 300$ m at 1 MHz).

Here we point out that the creation of an artificial ionospheric window to allow ground-based low frequency radio observations is now a realistic possibility.

Mendillo, Hawkins and Klobuchar[5,6] recently described the drastic depletion of the upper ionosphere (Fig. 1) brought about by the exhaust plume of the Saturn V rocket which placed NASA's Skylab Workshop into orbit on May 14, 1973. They concluded that the injection of molecular hydrogen and water vapour into the ionosphere increased dramatically the recombination rate of free electrons and oxygen ions in the F2 region.

Mendillo *et al.*[5] noted that, although the total electron content of the ionosphere decreased considerably, the critical frequencies for the E and F1 regions, as deduced from ionosonde measurements, did not change appreciably. The reason, they suggest, is that the ion–electron chemistry in these regions differs from that of the F2 region, and therefore the injection of H_2O and H_2 did not materially affect their loss rates. So it would be impossible to use this process during daytime to create a depleted plasma tube through the entire ionosphere.

During the night, however, the D, E, and F1 regions of the ionosphere disappear through natural recombination processes. The remaining night-time ionosphere, with a single peak around 300–350 km, owes its existence to the slow reaction rates of O^+ with O_2 and N_2 at these high levels. Consequently, a night-time injection of molecular hydrogen should greatly enhance the recombination rates at all heights and thus create a vertical tube of highly reduced plasma density through the entire ionosphere. This artificial ionospheric window should allow radio astronomical observations to be carried out from the ground between 1 and 6 MHz, and possibly at even lower frequencies.

The advantages of ground-based observations are several, for example calibration techniques are more reliable and antennas are free of plasma interference problems. The most important gain, however, might be the much improved directivity which could be achieved with simple interferometric techniques or with some of the already existing antenna arrays for long radio waves.

To take advantage of all this, one would have to create artificial ionospheric holes over existing antenna sites for low frequency radio observations. One long range possibility is to use the Space Shuttle, which NASA expects to have operational in the early 1980s and, in conjunction with the AMPS program, arrange to have an occasional hydrogen release over a low frequency radio observatory.

On the other hand, it seems logical to try to benefit from the present solar minimum when the ionospheric cutoff frequencies are at their lowest values. It seems, therefore, that for the next few years the best approach would be to launch rockets carrying a hydrogen payload from sites near suitable radio-astronomical facilities. These could be relatively small rockets able to carry a payload of about 100 kg to a height of about 300 km. As a first step it seems reasonable to use the 1,000-foot Arecibo telescope, which has a low frequency feed capable of operating at frequencies as low as 5 MHz (F. Drake, personal communication). The Arecibo observatory also offers the advantages of rocket launching facilities and continuous ionosonde monitoring of the ionosphere.

The height of the gas release should probably be about 50–100 km below the maximum of the night-time ionosphere, and preferably a continuous release over this altitude range. The reason is that the diffusion of H_2 through the ambient atmosphere strongly favours the upward direction[6], because of the exponential decrease of atmospheric density with height.

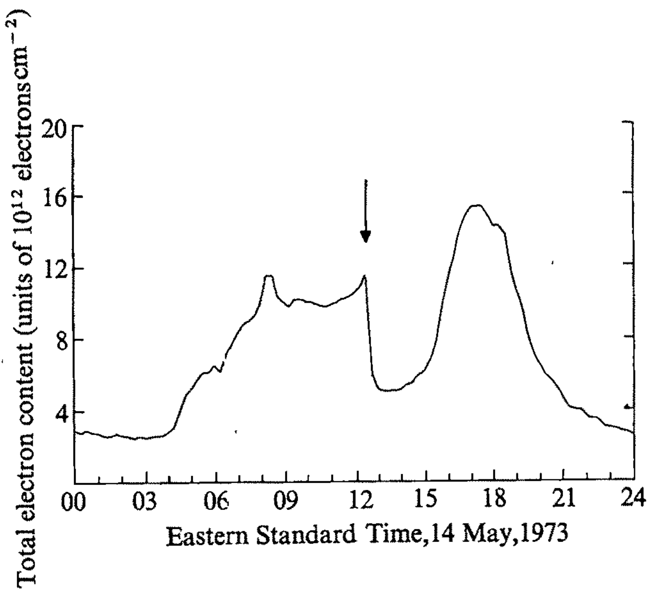

Fig. 1 Total electron content data obtained from the Air Force Cambridge Research Laboratory Sagamore Hill Radio Observatory in Hamilton, Massachusetts, looking toward the geostationary satellite ATS-3 on May 14, 1973. Arrow marks time of Skylab launch.

Using the simplifying assumption of spherical expansion in a uniform medium, the Skylab effect over a particular site could be accounted for by 1–2 s of the Saturn V exhaust,[5] that is, by a local injection of 40–80 kg of H_2 and 1–2 tons of H_2O. The release of 100 kg of hydrogen (3×10^{28} H_2 molecules), 50–100 km below the peak of the night-time ionosphere, should therefore create a vertical tube approximately 200 km in diameter with substantially reduced electron densities.

Considering this tube to have a length of 1,000 km (a volume of 3×10^{22} cm^3), such a release would produce an average density of about 10^6 H_2 cm^{-3}. The decrease of the electron density N with time at a given height is

$$dN/dt = -\beta N \qquad (1)$$

The recombination coefficient β is given by the expression

$$\beta = k\,[H_2] \qquad (2)$$

where $[H_2]$ is the concentration of hydrogen molecules and $k = 2\times10^{-9}$ cm^3 s^{-1} is the rate constant[7] for the reaction

$$O^+ + H_2 \rightarrow H + OH^+$$

With these values $\beta = 2\times10^{-3}\,s^{-1}$. This implies that the electron density near the peak of the night-time ionosphere ($\sim 10^5$ electrons cm^{-3}) would decrease to 5×10^3 in less than 0.5 h, and the density near 1,000 km ($\sim 10^4$ electrons cm^{-3}) would reach the same low level in less than 10 min. Of course, near the core of the tube the electron density should decrease much faster and to much lower levels, since the concentration of H_2, and therefore the value of β, would be much larger in this region.

We estimate that this tubular depletion should last for several hours. It would depend, among other factors, on the inclination of the Earth's magnetic field, which governs the diffusion of the surrounding plasma into the hole. The Skylab effect lasted 2–3 h, in spite of the fact that it occurred around local noon when the ionising radiation of the Sun is most effective.

Thermal regime of the Earth's interior

SEVERAL recent and apparently unrelated geophysical observations and deductions, when considered together, necessitate a fundamental re-examination of our ideas about the thermal state of the Earth's deep interior.

In summary they are:

(1) Precession must be discounted as a power source for the geomagnetic dynamo[1], leaving core convection as the only plausible basic mechanism. Therefore the temperature gradient in the outer core cannot be less than adiabatic.

(2) The thermodynamic Grüneisen parameter for the outer core is about 1.4 and is only slightly pressure dependent (R. D. Irvine and F.D.S., unpublished).

(3) The resulting adiabatic gradient is much steeper than the Fe melting point gradient[2] or the Fe–S eutectic gradient[3].

(4) Continents and ocean floors are both mobile, although the ocean floors are much more so[4], so that equality of the continental and oceanic heat fluxes which is observed[5] (in spite of gross differences between the radioactive constituents of the continental and oceanic crusts) cannot be explained in terms of an association of depleted regions of the mantle with continents.

(5) Hot spots, across which the tectonic plates move, are not themselves moving perceptibly with respect to one another and are presumed to mark features of a rigid lower mantle[4].

(6) A weak layer (asthenosphere) in the upper mantle allows virtually perfect isostatic balance of continent-sized blocks[6] but the lower mantle must have greater strength. Low degree harmonic features of the geoid are supported by stresses at depths of several hundred kilometres[7].

(7) Radiative transfer does not cause a dramatic increase in the thermal conductivity of mantle material at high temperatures[8,9].

As long as there remained a possibility that the geomagnetic dynamo is driven by precession[10], the fluid, outer core could be supposed to be stably stratified with a subadiabatic gradient. Although unconventional, the operation of a dynamo with the core in such a state could not be precluded[11] and the 'core paradox'[2,12] was avoided. This paradox arises because the adiabatic gradient in the core is much steeper than the melting point or eutectic temperature gradient, so that the conventional explanation of the solidity of the inner core as a pressure solidification of material from the outer core breaks down if the outer core is supposed adiabatic. But there now seems no possibility that precessional dissipation suffices for dynamo action. A 'rigid' core calculation indicated that the available power might be 3×10^{10} W (ref. 13), but Rochester[1] reported that proper inclusion of the internal core motions associated with core coupling to the mantle reduced the power estimate to less than 10^8 W, which certainly does not suffice to maintain the dynamo. Thus the temperature gradient of the outer core cannot be less than adiabatic.

So, how does one explain the apparently solid inner core? Elsasser and Isenberg[14] favoured an electronic phase transition in iron to the $3d^8$ state—collapse of all of the conduction or valence electrons into vacant 3d states. Probably because very little is known about such transitions (although one has been identified in caesium[15]) this suggestion has languished in obscurity; but now it emerges as the only real survivor. But it completely removes previously assumed constraints on the temperature of the core, based on the assumption that the inner core boundary represented the intersection of the temperature profile with the solidus of an iron-rich mix. Whether the inner core is really a crystalline solid must be doubted in view of its very high Poisson's ratio[16], which suggests some residual fluid character, but in any case extrapolation of ordinary melting point or eutectic data is irrelevant to an electronic phase transition.

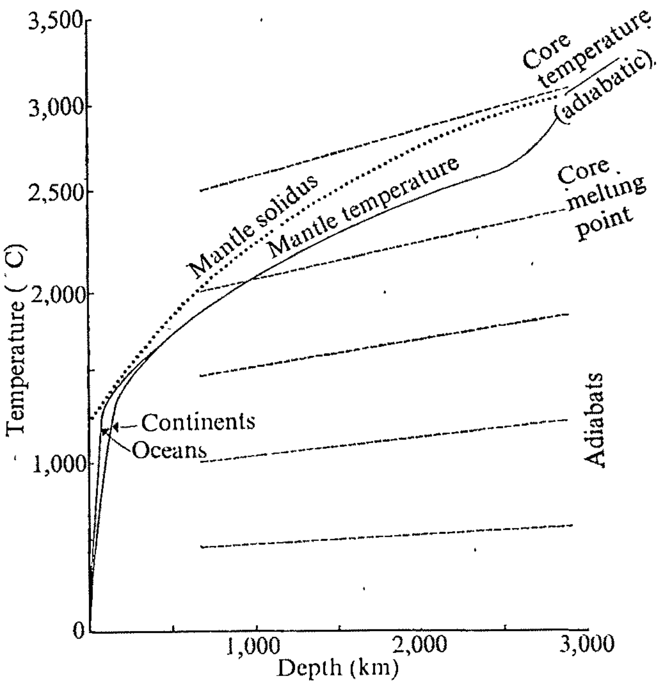
Rejection of core-constrained temperature profiles clears the way for an alternative approach, based on recent observations on the behaviour of the mantle. First, we note that the heat flux from the mantle into the continental crust is only about 0.015 W m^{-2}, the balance of the total geothermal flux (about 0.06 W m^{-2}) being provided by crustal radioactivity. But, since the continents ride about on rigid slabs of lithosphere, this mantle heat flux must be transmitted from depth by conduction. With an assumed conductivity of 2.5 W m^{-1} deg^{-1}, the required lithospheric temperature gradient extrapolates to temperatures of partial melting (~ 1,300 °C) at a depth of 150 km or so. This determines the thickness of the continental lithosphere, the more fluid asthenosphere below it being in convection. On the other hand the oceanic lithosphere is not a permanent feature. After formation at an ocean ridge, any section of it survives only for about 10^8 years before plunging back into the mantle at a subduction zone. If we suppose that its duration is simply its thermal relaxation (cooling) time τ, then with a thermal diffusivity representative of igneous rock, $\eta=1.2\times10^{-6}$ m^2 s^{-1}, we can estimate the thickness of the oceanic lithosphere as:

$$D=(\tau\eta)^{\frac{1}{2}}=70\text{ km}$$

It is important that these simple arguments give reasonable lithospheric thicknesses and are in accord with the equality of continental and oceanic heat fluxes without requiring any difference in radioactive heat generation in different parts of the mantle. Not only does it remove the implausible constraint to tectonic and convection theories that the continents must move about with their own sections of mantle, depleted in radioactivity, but also there is no reason for the temperature difference between the subcontinental and suboceanic mantle to extend into the lower mantle.

Increasing strength with depth below the asthenosphere (observation (6)) implies that the temperature profile diverges again from the solidus at greater depths. But we also require convective instability of the lower mantle to remove heat from the core, which, with a reasonably constrained conductivity[17], cannot be less than about 3×10^{12} W (ref. 18). In the case of the

Fig. 1 Suggested temperature profile of the mantle.



mantle, which has both a lower temperature and a smaller Grüneisen parameter, ~ 0.9 (R. D. Irvine and F.D.S., unpublished), than the core, we can hardly avoid the conclusion that the solidus gradient is steeper than the corresponding adiabat, at least in the upper levels, so that there is no difficulty in accepting an actual temperature gradient between the two. This is precisely the condition required for the establishment of narrow convective plumes[19]. The temperature gradient in the lower mantle gives increasing strength with depth, inhibiting convection in the whole mantle, but core heat must melt or nearly melt a thin layer at the base of the mantle. As this melted layer tends to rise, it finds that it is in a super-adiabatic gradient and so is convectively unstable, but that as it rises its melting point falls more rapidly than its actual temperature (decompression being approximately adiabatic) so that it becomes increasingly fluid and therefore heats a narrow channel to guide subsequent flow.

These considerations are summarised by the illustrative temperature profile in Fig. 1. This curve can be extended into the outer core for any assumed depth of convection by taking the adiabatic gradient (for which the assumption of a constant Grüneisen ratio of 1.4 suffices), but the required heat sources may be distributed through the outer core only, so that eventually we must reach a depth at which the heat flux is insufficient to support the adiabatic gradient. Below this the heat flow is diffusive only, but detailed calculations[20] show that the depth of transition from convective to diffusive regimes is very sensitive to the total heat flux; a 10% increment above the flux required just to maintain diffusion down the adiabatic gradient causes convection over most of the outer core. Thus it is reasonable to assume an adiabatic gradient through the whole outer core. This gives a temperature ratio between the inner core boundary and core–mantle boundary, $T_{IC}/T_{C-M}=1.33$ and, with the values in Fig. 1, an inner core temperature of 4,100 °C.

It may be noted that the necessity for 3×10^{12}–5×10^{12} W of radiogenic heat in the core seems unavoidable. Thus the geophysical requirement for potassium in the Fe–S outer core seems even stronger than the geochemical evidence[21-23] for it.

Wire strainmeters on ice

We have installed a geophysical wire strainmeter for brief periods on the Roslin glacier, Stauning Alps, East Greenland and on the sea ice at Bylot Sound, Thule, North-west Greenland. The technique promises to yield information concerning the mechanism of deformation and flow in ice.

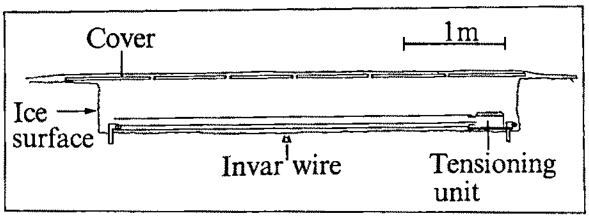

Fig. 1 The strainmeter installed on the glacier.

Previous studies of ice flow have involved intermittent measurements of surface markers[1], but although such methods illustrate the presence and rate of cumulative motion over large distances they do little to reveal the internal mechanism of flow. Few measurements have been made of the detailed strain behaviour of ice continuously at a point *in situ*[2,3]. For example, it is not known whether glacier flow is episodic and rapid with long periods of quiescence, or whether continuous creep occurs.

The wire strainmeter used in the experiments was designed for studies of earth strain (ref. 4 and G. C. P. King and R. G. Bilham, to be published) and has a measuring range of 10^{-4} strain (Fig. 1). The strainmeter uses 0.5-mm Invar wire held in tension by a lever and weight system. Rotation of the tensioning lever is detected electronically, amplified, filtered and recorded on a chart recorder. Using it as a 10-m strainmeter results in a maximum strain resolution of 10^{-10} in an environment where the temperature is stable. The temperature coefficient of the instrument is approximately 5×10^{-7} per °C. The instrument weighed only 10 kg and was easily transported to the sites.

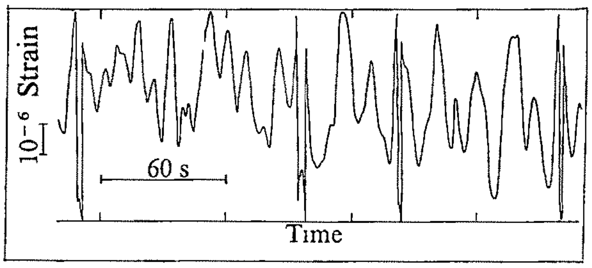

Fig. 2 Continuous record of strain changes measured on the sea ice in Bylot Sound, North-west Greenland in June 1974. The abrupt changes are d.c. shifts automatically introduced to keep the record on the chart.

The instrument was connected to the ice using two ice screws—a quick and simple means of obtaining the attachment stability required. Temperature stability (0 ± 0.5 °C) was obtained by building a cover when the strainmeter was on the sea ice and digging a 0.5-m trench and covering it when the strainmeter was installed on the glacier.

In June 1974 the instrument was installed on some first-year ice in Bylot sound (76°27′ N, 69°30′ W). The ice there was 0.86 m thick 71.7 m from the ice edge and 140 m from the shore. Some of the data obtained are shown in Fig. 2. Figure 3 is a frequency transform of approximately 1 h of data. The high-frequency part of the spectrum is suppressed by electronic filtering (−3 dB at 6-s periods). The spectrum is similar to that obtained from sea waves[5] with a dominant peak at approximately 16 s. There is a pronounced minimum between periods of 1 and 2 min, and the waves of longer period (20 min) present probably arise from seiches in the bay[6].

In July and August the instrument was taken to the Roslin glacier (71°51′N, 24°59′W). The glacier is a typical sub-polar–valley glacier 33 km long, 2 km wide and 300 m deep at the site. The surface velocity at the site, determined from four years of stake measurements, is about 9.5 m yr⁻¹. The instrument was installed centrally, parallel to glacier motion, slightly below

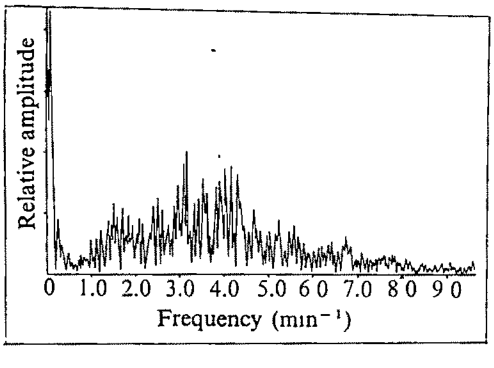

Fig. 3 Frequency spectrum of approximately 1 h of data obtained from the strain changes observed on the sea ice. The large peak on the left is probably due to seiches in the bay.

its junction with the Dalmore glacier and just below the firn line. Approximately three weeks of data were obtained with a chart speed of 18.8 cm h^{-1}. The records show long periods of slowly varying strain (10^{-7} a week) which may be partly instrumental drift, with occasional rapid, smooth excursions which recover after several minutes. A representative event, possibly indicating the transient strain field from a propagating creep event within the glacier is shown in Fig. 4. The temperature was monitored continuously and showed no such fluctuations. An array of strainmeters would make it possible to test this hypothesis.

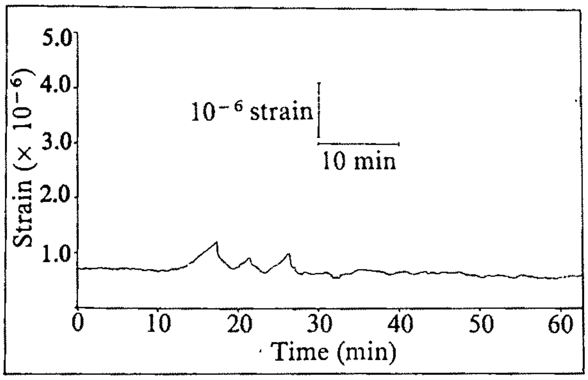

Fig. 4 Creep event observed on the strain record of a wire strainmeter on the surface of the Roslin glacier, East Greenland in August 1974.

The two preliminary experiments have convinced us that further studies with wire strainmeters on ice are justified. The study of creep processes in ice may have relevance to other disciplines where *in situ* deformation is slower, for example studies near geological faults[7].

Late Cretaceous and Palaeogene palaeolatitudes of the Ontong Java Plateau

THE Pacific plate has undergone a substantial northward displacement during the late Mesozoic and the Cainozoic. Here we give additional documentation for such motion based on palaeomagnetic measurements of a sequence of sedimentary and basalt samples collected from middle Oligocene to Aptian sections of Deep Sea Drilling Project (DSDP) site 289 (ref. 1; 00° 29.92′S, 158° 30.69′E) drilled on the Ontong Java Plateau.

The plateau is a major submarine feature more than 1×10^6 km^2 in area. It consists of an unusually thick crustal section overlain by approximately 1 km of flat-lying calcareous sediments[2]. We investigated site 289 mainly to determine the latitude of formation of the plateau, so our present results pertain only to the older site 289 cores. Initially, in addition to not knowing the extent of drilling disturbance within the sections, it was uncertain whether meaningful palaeomagnetic results could be obtained from such highly calcareous sediments. Palaeolatitudes determined from the measured palaeomagnetic inclination values of these samples, however, not only yielded an indication of the latitude of formation of the plateau but also provided a partial record of its subsequent northward movement during the interval from about −110 Myr to about −30 Myr. Other palaeolatitude trends measured in sediment samples from DSDP sites have also been attributed[3–5] to plate motion.

Ages were determined from the biostratigraphic report[1] by interpolating between well known planktonic foraminiferal datum planes[6]. The oldest core, core 30–131, reached upper Aptian sediments containing the foraminifer *Hedbergella trochoidea*. In keeping with current calibrations of Cretaceous stage boundaries[7], an age between about 108 and 106 Myr is assigned to the lowermost sediment samples.

We do not yet have evidence with which we can firmly establish the age of the basalt, and thus determine whether there is a hiatus at the basalt–sediment contact. Initial radiometric age determinations resulted in dates of −85±10 and −77±9

Fig. 1 Palaeolatitudes plotted against time for samples from DSDP site 289, Leg 30 (00°29.92′S, 158°30.69′E). Intensity of magnetisation of the sediment samples was generally of the order 1×10^{-7} gauss. But the angular difference between multiple measurements of single samples at the 100-oersted level typically did not exceed 2°. ●, Sediment; ■, basalt; ▲, mean of basalt.

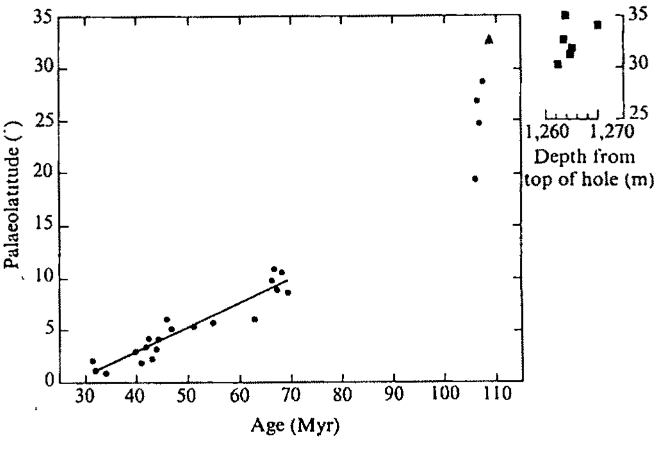

Table 1 K–Ar age results from the basalt, DSDP Hole 289, Core 132, Section 4, 141–143 cm

Subsample number	Weight (g)	Potassium (%)	Radiogenic argon ($\times 10^{-7}$ cm^3 g^{-1})	$^{40}Ar_{rad}/^{40}Ar_{total}$	Age±1 s.d. (Myr)
1	1.6269	0.0678 0.0757 0.0613	2.13	0.49	77± 9
2	2.8264	0.0650 0.752	2.36	0.69	85±10

The sample was holocrystalline with alteration confined to minor oxidation in the groundmass. The potassium content was determined by atomic absorption analysis; argon was released by induction heating, purified, and analysed using procedures of Keeling and Naughton[9]. An error analysis, similar to that of Cox and Dalrymple[10], indicated that the estimated analytical standard deviation arises almost entirely from uncertainties in the potassium measurements.

Myr for splits from one of the seven basalt samples (Table 1), but the conflict of these dates with the biostratigraphic ages for the oldest overlying sediment suggests strongly that they do not indicate the true age of the basalt. We tentatively assume the absence of an extensive basalt–sediment hiatus, and have therefore assigned an age of 109 Myr to the basalt.

Very little change in direction from that of the NRM was noted during stepwise alternating-field (a.f.) demagnetisation of each sediment sample[8]. Median destructive fields averaged about 300 oersted. There were no significant variations in demagnetisation characteristics throughout the sedimentary section, nor were there any visual signs of chemical alteration; further details pertaining to the palaeomagnetic data and techniques are reported elsewhere[8]. We attribute the tendency for palaeolatitude values to increase with age (Fig. 1) to relative motion between the region of the Ontong Java Plateau and a stationary planetary magnetic field. But the observed trends (Fig. 1) could be explained equally well by postulating a fixed lithosphere and a mobile field, or by motion of both field and lithosphere. Further, the present palaeolatitudes, determined assuming the Earth's field to be a geocentric axial dipole, would be in error by several degrees if the Early Cretaceous and Palaeogene field was, as has been proposed for the Neogene, not centred but offset into the Northern Hemisphere[11].

The slope of the least squares fit in Fig. 1 corresponds to an average rate of motion of about 2.5 cm yr^{-1} for the interval between about −70 and −30 Myr. The mean palaeolatitude anomaly[12] for the samples in this time span is consistent with this rate. The absence of data between about −105 and −70 Myr results from a late Aptian to late Campanian hiatus. But the palaeolatitudes for the oldest four sediment samples and mean palaeolatitude for six of the seven samples of basalt (one sample was excluded on the basis of its seemingly unstable remanence[8]) all lie above the best-fit line if it is extrapolated through the missing interval. This seems to indicate that the rate of crustal movement was more rapid during part or all of the time before −70 Myr. In turn, it is conceivable that the abrupt increase in palaeolatitudes reflected in the last four sediment samples merely represents a greater scatter of the data. This apparent scatter is, however, unrelated to biostratigraphic age control and is not the result of changes in sediment magnetic properties[8].

Because the ages of the youngest of our samples do not extend into latest Oligocene, the level reached by the known sediment-based polarity reversal sequence[13], only relative polarity can be defined from changes in the sign of the inclination. True polarity must, however, be determined in order to define the direction of motion of the lithosphere (northward or southward); our five oldest sedimentary samples are late Campanian, Albian, and late Aptian in age, all times of almost exclusively normal polarity[14-16]. It seems likely that these samples, and presumably also the basalt samples, are of normal polarity. They must have originated in the Southern Hemisphere, because their inclinations are all negative[8], and been displaced northward to the coring site.

Y. Lancelot and colleagues (unpublished) have determined rates and poles of rotation for the Pacific plate based on the northward shift, with increasing age, of equatorial sediment facies as observed in cores from DSDP sites, including site 289. Our rate of about 2.5 cm yr^{-1} between about −70 and −30 Myr is approximately half the northward rate predicted by their model for the site, but experimental errors in either method may be responsible for part of the disparity. The approximate latitude of formation we determine for the plateau (about 33° S), is in reasonable agreement with the approximately 40° S latitude suggested by Lancelot and colleagues.

Although at present we lack palaeomagnetic data necessary to describe the Neogene tectonic history of the Ontong Java Plateau, such results are available for the Central Pacific Basin, located east of the plateau and separated from it by the southern extension of the Marshall–Gilbert–Ellice Islands Ridge.

Palaeomagnetic evidence from deep-sea cores from the Central Pacific Basin indicates that the basin underwent continual northward displacement throughout the past 30 Myr at a rate of about 7 cm yr^{-1} (ref. 17). Unpublished work by Lancelot and colleagues, and other stratigraphic evidence for the migration of the zone of maximum sediment accumulation as observed in central Pacific DSDP cores[18], confirm the northward displacement of the basin. But those models (Lancelot and colleagues, and ref. 18) suggest motion at a much slower rate than our postulated 7 cm yr^{-1}.

Dating a stalactite by electron paramagnetic resonance

OPTICAL and electron paramagnetic resonance (EPR) properties of natural and synthetic calcite (limestone, $CaCO_3$) have been studied extensively and it is known that ionising radiation in the form of cosmic rays or from radioactive elements introduces defects such as CO_3^- (a hole centre) and CO_3^{3-} (an electron centre), which are stabilised by impurities to form sources of thermoluminescence[1,2]. There are four thermal glow peaks above room temperature[3,4], some of which can be used to trace the history of calcite[5]. Here I report the presence of a radiation-induced defect in the growing stalactites of Japan's main calcite caverns and show that estimation of the accumulated defect concentration at several positions, using EPR, makes it possible to determine the age and growth rate of a stalactite.

Figure 1 shows EPR derivative spectra of the limestone at Akiyoshi karst plateau (Carboniferous to Permian) and of a stalactite at Akiyoshi, the biggest cavern in Japan. A prominent feature is the hyperfine sextet and the forbidden transitions ($\Delta m = \pm 1$) associated with the Mn^{2+} nuclear spin ($I = 5/2$). The EPR intensity of Mn^{2+} is much stronger in a limestone than in a stalactite, possibly because of the repulsion of Mn^{2+} in the recrystallisation of $CaCO_3$ during stalactite growth. Another feature of the EPR spectrum of the stalactite is the relatively intense signal with $g = 2.003 \pm 0.001$. The signal intensity is reduced by thermal annealing of the stalactite above 500 K, where thermoluminescence is observed. It is, however, also enhanced strongly when the stalactite is irradiated with ^{60}Co γ rays. Marshall *et al.*[1,2] observed that the CO_3^{3-} centre was stabilised at up to 500 K by a Y^{3+} impurity in the irradiated calcite crystal. The g tensors were $g_{xx} = 2.0012$, $g_{yy} = 2.0024$ and $g_{zz} = 2.0038$. The present g value of the polycrystalline calcite, and the thermal stability, agree within experimental error.

The effect of stresses caused by dynamic metamorphism[6,7], which also creates the ionisation and defects responsible for the high temperature thermal glow peak at 700 K in calcite, need not really be considered for a cavern stalactite; in any case the stalactite did not show any enhancement in EPR signal on grinding. The most plausible explanation for the presence of this radiation-induced defect in a stalactite is, therefore, natural radiation—cosmic rays and the radiation from radioactive elements such as ^{40}K, ^{238}U and ^{232}Th. Zeller used EPR to study the natural radiation damage of zircon, apatite and also carbonate, and observed a similar spectrum in limestone[5]. He also suggested the use of EPR for dating geological materials.

The observation that the EPR signal of $g = 2.003$ in a natural limestone (Permian; Neoschwagerina craticulifera Zone) is very weak (Fig. 1*a*) is puzzling, as the limestone has been exposed to natural radiation for about 2×10^8 yr. This is easily understood, however, in view of the fact that it was not possible to create this signal in the limestone by artificial γ irradiation. As the concentration of Mn^{2+} and other impurities such as Fe^{2+}, Si^{4+} and Al^{3+} in a limestone is very high, absorbed radiation energy (creating electrons and holes) would be consumed very efficiently at impurity sites at around room temperature.

Figure 2 shows the relative intensity of this signal as a function of the radial distance from the surface of a stalactite in the K branch of Akiyoshi-Do Cave. In every growing stalactite taken from four main caverns in Japan, the signal intensity at the surface is very small but increases linearly inside the stalactite. Since the surface of a stalactite is recent, and the calcite becomes older as one goes inside, this result clearly indicates that the EPR signal is associated with a defect formed by natural radiation and that the signal can be used for dating. The change in the signal intensity with radial position cannot be ascribed to the distribution of any specific impurity.

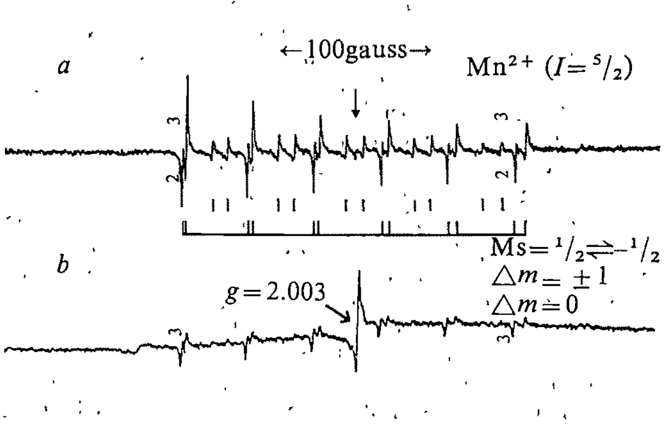

Fig. 1 EPR spectra of limestone (*a*) and a stalactite at Akiyoshi Cavern (*b*). The EPR hyperfine line sextet of Mn^{2+} ($\Delta m = 0$) and the forbidden transitions ($\Delta m = \pm 1$) are indicated in the figure. The signal with $g = 2.003$ (arrow) is associated with defects produced by natural radiation.

Table 1 Age and radial growth rate in time units of natural radiation dose (rad) for growing stalactites in Japan's main caverns

Cavern	Location (prefecture)	Terrestrial background radiation (m rad yr^{-1})*	Stalactite age (rad)†	Growth rate†‡ (μm rad^{-1})
Akiyoshi (Kurotani branch)	Yamaguchi (West Sanyo)	69	7×10^4	(*a*) 1.8 ±0.5 (*b*) 0.18±0.05
Hiraodai	Fukuoka (North Kyushu)	48	2×10^5	(*a*) 0.4 ±0.1 (*b*) 0.15±0.05
Ryusen	Iwate (East Tohoku)	32	3×10^4	(*a*) 1.5 ±0.5 (*b*) 0.8 ±0.3
Garashigama	Okinawa (South Island)	—	2×10^3	(*a*) 10.0 ±3.0

*γ-ray exposure rates arising from terrestrial radionuclides at 1 m above ground in each district[8]. Radiation damage would be caused mainly by α-rays from uranium and thorium in the stalactites, so this value is to indicate the geographical difference and is not a conversion factor for the actual age and annual growth rate.

†Time is expressed in rad, corresponding to the ^{60}Co γ-ray exposure to water. Actual age or growth rate must be obtained by dividing or multiplying by the annual radiation dose to the stalactite from both inside and outside. Estimation of actual age and growth rate is discussed in the text.

‡The growth rates determined are for the radial direction. The longitudinal growth rate is generally 8~10 times larger than the radial one. *a*, Radial growth rate of the stalactite close to the surface; *b*, radial growth rate inside.

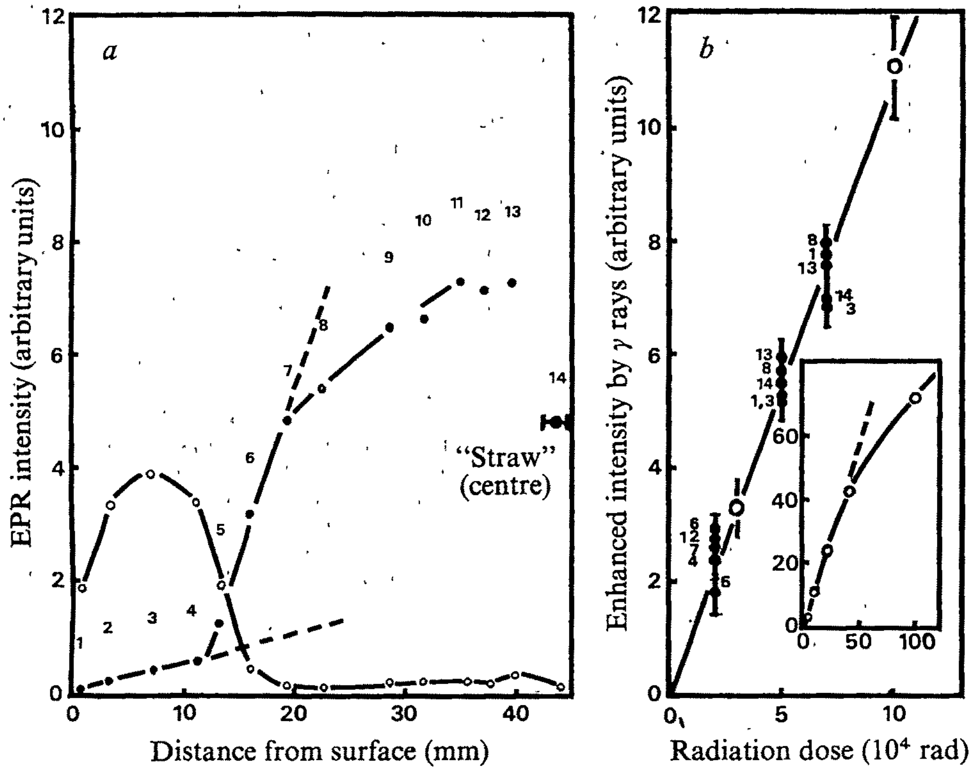

Fig. 2 *a*, Change in the EPR signal intensity as a function of distance from the surface of a stalactite at Akiyoshi. The signal intensity of Mn^{2+} impurity is also shown (○) ●, *g* = 2.003. *b*, Enhancement of the EPR signal by the exposure to γ rays from ^{60}Co for samples mixed (○) or taken from different positions (●). A straight line can be drawn (within ±10%) up to 10^5 rad. The EPR intensity is thus proportional to the dose of natural radiation, and so to the age, in this dose range. The stalactite's radial growth rates were deduced from the initial and subsequent slopes in *a* and the age was determined from the maximum signal intensity close to the centre "straw" position. The enhanced intensities of mixed powders are also shown in *b*.

Figure 2*b* shows the enhancement of the signal intensity brought about in samples from several parts of the stalactite, numbered 1 to 14, by exposure to ^{60}Co γ rays. The growth of the signal intensity is almost linear up to 10^5 rad and then deviates slightly from linearity. The growth rate above 10^6 rad is about half the initial rate and shows signs of saturation. The variations among samples from different locations in sensitivity to γ-ray exposure is within experimental error. Since the samples were usually taken within width bands of 1~2 mm, sensitivity differences arising from the microdistribution of impurites may be averaged out. As the signal intensity of the unirradiated stalactite corresponds to that observed after γ-ray exposure of ~ 10^4 rad, I simply assume linearity with the radiation dose. Thus, one can estimate the total dose of natural radiation received by a sample by comparing the signal intensity of the natural stalactite with the intensity as enhanced by γ radiation. Samples were kept in the dark for a few days after the exposure to γ radiation so that unstable defects could fade away. The signal intensity relative to that of Mn^{2+} was measured after irradiation. It was assumed that the signal intensity of Mn^{2+} is not altered by irradiation.

One can also estimate the age or annual growth rate of any part of a stalactite if the annual dose of natural radiation is known. Unfortunately, I do not at present know the radiation type or dose in Japan's caverns. Therefore, I show in Table 1 the age and growth rate on a time scale of the radiation dose (rad) for cavern stalactites. Terrestrial background γ radiation dose rates in the areas[8] are also given. The concentrations of U, Th and K in soils at West Sanyo (Yamaguchi area) was 1.3, 9.3 and 2.2 p.p.m., respectively; these values are higher than the averages for Japan (1.3, 5.6 and 1.4 p.p.m.). In East Tohoku, the concentrations are lower than average. The radiation source in the stalactite would be mainly these ions.

Aitken used 1 rad yr^{-1} as the annual dose rate for thermoluminescence dating of pottery[9] and if this value is used, the numerical values in Table 1 are the actual age and annual growth rate. This value would, however, be an overestimation for stalactites, as the U content is an order of magnitude lower than in pottery[10]. We are in the process of measuring the concentrations of these radioactive elements by γ-ray spectroscopy[8], and also the background radiation in Akiyoshi cave with a thermoluminescence dosimeter (TLD) of $CaSO_4$ (Tm) embedded in a stalactite.

Linear energy transfer (LET) effects on the radiation damage of a stalactite by α rays, by β rays and by γ rays of different energies must be considered. For example, the sensitivity of $CaSO_4$ TLD material to low energy photons is about 10 times that to ^{60}Co γ rays. On the other hand, the sensitivity to α or β rays is less than that to ^{60}Co γ rays, according to luminescence dosimetry studies. This holds good for $CaCO_3$, so the accurate estimation of the annual radiation dose for a stalactite is a topic to be treated separately.

The signal intensity at the centre ("straw") is about two-thirds that at a position close to the centre, as shown in Fig. 2. This is much more of a variation than that among samples taken from different distances. Polarisation microscope studies of a polished thin slice of a stalactite indicate that the *c* axis of the calcite crystals is almost in a radial direction, except in the centre ("straw") position, where it is longitudinal. The results suggest that the centre part was made later, in agreement with the model of stalactite growth.

Figure 2*a* indicates that there is a distinct change in growth rate, the slow increase of the EPR signal near the surface indicating rapid growth of the stalactite. The same distinct change was observed in a stalactite at Hiraodai (Kyushu), very close to Akiyoshi (Yamaguchi). The change is, however, not as clear for stalactites at Okinawa and in northern Japan. The change in growth rate may be associated with a drastic change in the climate, which favoured the recent rapid growth.

The signal intensity increases linearly after this sharp change but saturates very close to the centre, either because of rapid growth there or because of an equilibrium between fading and defect formation. The annealing experiment indicates that part of this signal intensity decays with the thermoluminescence at 500 K. The centre is completely destroyed by 10 min of pulse annealing above 700 K. A fading time of about 3×10^5 yr is expected if the defect produced is related to the thermoluminescent glow at 600 K (refs 3 and 4). A stalactite also has a recently grown part, however, and this can be used for determination of the growth rate. Defects stable at higher temperature could be used for dating older parts of a stalactite, or limestone.

I thank Professor N. Itoh and Dr M. Ohta for their help and partial support of this research. I also thank Professors T. Higashimura and H. Shima for discussions.

Trace elements in total particulate material from surface sea water

THE euphotic zone is an important marine environment in which the photosynthetic planktonic population of the oceans is in contact with inorganic solids. These inorganic solids, together with a proportion of the biomass, settle out and are eventually incorporated into marine sediments. There have been various investigations into the chemistry of marine plankton[1-3]. Little is known, however, of the elemental composition of the total particulate material from the euphotic zone on a worldwide basis. Because of this lack of data average trace element concentrations for particulate material from relatively large oceanic regions are useful because they give an indication of values to be expected in the euphotic zone in general. Here, we present preliminary data on the trace element composition of some total particulate material from the surface (0 to ~5 m) layers of the North Atlantic, South Atlantic, Indian Ocean and China Sea.

Samples were collected on board MV Cyclops during March and July, 1972, by pumping seawater from a position by the ship's bows (which minimised contamination from the ship's sides) through plastic tubing to a continuous centrifuge. Particulate material was retained on plastic liners which were stored at ~12 °C until the solids were removed by washing with distilled water in the laboratories at Liverpool. The particulate material was dried at ~40 °C, finely ground, and the trace elements determined spectrographically using an argon–oxygen atmosphere. The ship's track and the sampling positions are shown in Fig. 1, and the trace element composition of the particulate matter is given in Table 1 where it is averaged for each oceanic region. The trace element compositions of some marine sediments and plankton are listed in Table 2.

Table 1 Trace element concentrations in the surface particulate material (concentrations in p.p.m.)

Oceanic region*	Mn	Cu	Co	Ga	V	Ba	Pb	Zn	Mean: %organic carbon
North Atlantic (10)	145	74	11	4	38	191	52	159	24
South Atlantic (4)	85	52	16	3	69	72	72	260	18

Total particulate material in the euphotic zone of the oceans consists of a mixture of continental weathering products (including organic and inorganic precipitates), authigenic inorganic precipitates, and organic components which include phytoplankton, detritus (dead organisms), zooplankton and bacteria. It is difficult to establish the trace element composition of any of the various components in this complex mixture because they cannot be completely separated from each other. Certain estimates can, however, be made by considering the average compositions of marine sediments and plankton. Continental weathering products brought to the oceans by river run-off have a variety of particle sizes. In general, the coarser material will tend to settle out close to the continental margins and, to a first approximation, its composition should be similar to that of the average near-shore sediment. On average, the particulate material is deficient in Mn, Ga, V and Ba, and is enhanced in Cu, Pb and Zn relative to near-shore sediments (Table 2). Finer particles of a continental origin can escape deposition on the shelf regions and be transported to pelagic areas by current systems in the upper water layers These particles, which include iron and manganese oxides, have relatively large surface areas and may be rich in adsorped trace elements (of river, estuarine and marine origin). These particles are eventually incorporated into deep-sea sediments. Relative to these sediments the particulate material is deficient in Mn, Co, Ga, V and Ba, contains about the same amounts of Cu and Pb, and is enhanced in Zn. Continentally derived aeolian dust particles will also make a contribution to the total particulate material in the surface layers of seawater.

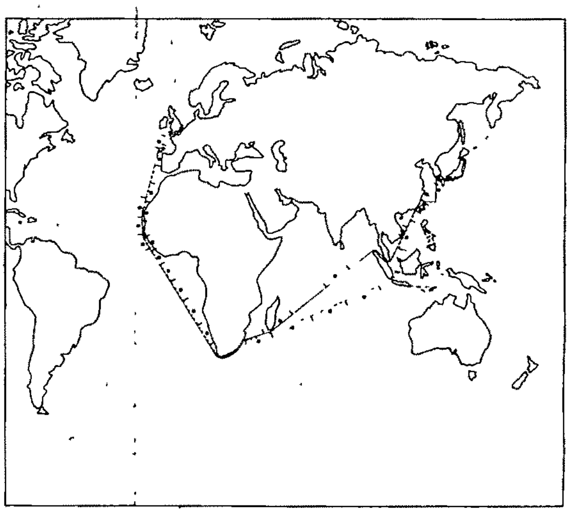

Fig. 1 Track of the MV Cyclops. Solid line, UK–Japan run; broken line, Japan–UK run. Particulate samples were collected over the intervals indicated by the lines perpendicular to the track; solid circles indicate the central positions of the sampling sites.

Particulate material in the upper layers of seawater undergoes considerable differentiation before and during its incorporation into marine sediments. This differentiation includes chemical changes which occur during its descent

Table 2 Trace element concentrations in surface particulate material, marine sediments and marine plankton (concentrations in p.p.m.)

	Mn	Cu	Co	Ga	V	Ba	Pb	Zn
Mean: particulate material; this work	529	109	13	5	63	126	58	220
Mean: surface water particulate material; Gulf of Maine[4]	540	480	—	—	—	—	—	360
Mean: near-shore sediments[5]	850	48	13	19	130	750	20	95
Mean: Atlantic deep-sea sediments[5]	4000	130	38	21	140	700	45	130
Range: marine plankton[1–3]	4.5–17	12–65	<1–15	—	—	6–100	4–219	39–1510

down the water column, at the sediment surface–seawater interface, and during burial. For example, the particulate material contains an average of ~30% organic matter[6], whereas deep-sea sediments usually have only ~1% of this component. Further, carbonate and siliceous shell debris are often lost from the sea floor by dissolution. It is not known whether or not the trace elements associated with these components are retained in the sediment residues. So there are inherent difficulties in comparing the trace element compositions of particulate material from surface waters with those of marine sediments. Nonetheless, it may be concluded that, in general, the total particulate material is enriched in Zn, and to a lesser extent Pb and Cu, relative to marine sediments.

There are considerable variations in the published concentrations of trace elements in marine plankton, and for this reason a range of values rather than an average is given for each element in Table 2. In spite of this difficulty, certain overall trends in the distribution of trace elements in the plankton can be evaluated from these figures; relative to marine sediments this component is considerably deficient in Mn, and is enriched in Pb and Zn. The two latter elements are also enriched in the particulate material.

So it seems that the trace elements in total particulate material from the surface layers of seawater have a number of sources: Mn, Co and V are probably mainly present in continentally derived material and authigenic precipitates; Pb and Zn are probably located largely in plankton; and Cu and Ba are partitioned between the two components.

We thank the Blue Funnel Line for permission to make collections from their ships, the Master, Officers and Crew of the MV Cyclops, A. J. Woodward for help in the collection of samples and the Natural Environment Research Council for financial support.

Charge relationships of phosphate sorption

IT is generally accepted that the mobility of phosphate in soil systems is largely governed by sorption-desorption reactions[1,2], but the mechanisms involved in these reactions have remained largely obscure. Studies[3–5] have shown that sorption of phosphate by soils can be described by at least two Langmuir equations over a solution phosphate concentration range of up to approximately 8×10^{2} µmol l^{-1}. Interpretation of these data has been complicated by the lack of an equilibrium condition, implicit in the Langmuir equation, and by the limited number of data points on the sorption isotherms. An alternative approach described here provides a reliable basis for the development of the sorption mechanisms.

Study of anion sorption by hydrous metal oxides, as developed by Hingston *et al.*[6–3] is based primarily on shifts in points of zero charge and on the "adsorption envelope". This approach has been questioned[9], and the extrapolation of these concepts, developed using pure components, to soils has not been tested adequately. It has been demonstrated[10] that measurement of the increase in negative charge that occurs as a result of phosphate sorption by soils, may be useful in evaluating the sorption mechanism.

Using experimental techniques described elsewhere[11], and a matrix solution of 10^{-1} M NaCl, we have found that phosphate sorption data, after transformation according to the Langmuir equation, for each of four contrasting New Zealand soils are described by three distinct linear relationships (denoted as regions I, II, and III). The sorption data represent an equilibrium condition estimated by a graphical approach[11], and cover in detail a solution phosphate concentration range of up to 8×10^{2} µmol l^{-1}. Interaction of regions was eliminated using a method of successive approximations. The Langmuir sorption constants, relating to sorption energy (k) and sorption maximum (b) for each region, are given in Table 1. The striking feature of the data is that the k values for each region were similar in spite of very wide differences in mineralogical components considered important in sorption of phosphate. The variation in k values

Fig. 1 Relationship between the amount of phosphate sorbed and the difference (ΔNa) between sodium uptake by the sorbent in the presence and absence of phosphate at the same level of sodium addition. Points A, B, and C refer to data in Table 2. *a*, Okaihau soil; *b*, Fe gel.

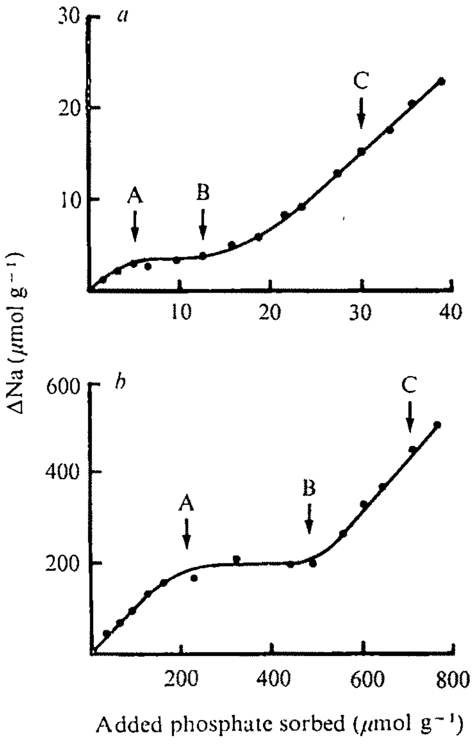

Table 1 Mineralogical components, *p*H, and Langmuir constants (*k* and *b*) for sorption of phosphate by four New Zealand soils

Soil	Mineralogical components	*p*H	k_I	k_{II}	k_{III}	b_I	b_{II}	b_{III}
				ml μmol^{-1}			μmol g^{-1}	
Egmont	Allophane	6.7	5,890	143	5.18	39.3	48.6	104
Okaihau	Kaolinite-gibbsite—secondary Fe_2O_3	5.1	7,380	208	5.02	21.4	33.3	55.9
Porirua	Micaceous vermiculite	4.6	3,280	145	2.51	4.19	9.19	17.1
Waikakahi	$CaCO_3$	8.1	2,970	158	8.90	1.40	2.61	10.5

Table 2 Sorption maxima for each of three regions of Okaihau soil and Fe gel (at 40 h in 10^{-4} M NaCl) and various data relating to Fig. 2

Sorbent	Region	*b* μmol^{-1} g	Saturation (%) at point A	B	C	ΔNa:phosphate*
Okaihau soil	I	4.19	93	100	100	0.76
	II	14.7	8	57	97	0
	III	22.4	<1	3	41	1.15
Fe gel	I	226	100	100	100	0.88
	II	242	5	100	100	0
	III	643	<1	5	39	0.96

*Average based on degree of saturation of regions I and III for various levels of overall phosphate sorption, calculated from respective *k* and *b* values.

between regions was approximately 20–50 times greater than that within a particular region. Each region corresponded to a well defined concentration range. For region I the concentration range was 0–0.7 μmol phosphate l^{-1}, for region II 1.5 to 25 μmol phosphate l^{-1}, and for region III 32 to >650 μmol phosphate l^{-1}. Within each concentration range at least 70 to 80% of the overall increase in sorption of phosphate was attributable to sorption in the corresponding region. Only the *b* values reflected the differences in the properties of the soils used.

These findings suggest that the origin of the deviation of phosphate sorption data from a single Langmuir equation arises from three distinct phosphate sorption mechanisms at sites which are common to each soil, rather than from phosphate sorption at different soil components, as suggested in other studies[3,5]. Although calcium carbonate is the dominant mineralogical component in Waikakahi soil, there is abundant evidence to suggest that this component is of minor importance in phosphate sorption[2], relative to the Fe and Al components present. The only possible sites for phosphate sorption common to all soils are those of the type M-OH (M = Fe or Al) which occur at the surfaces of hydrous metal oxides and short range order aluminosilicates, at the edge faces of crystalline aluminosilicates, and on Al (Fe) organic complexes. The *p*H dependence of charge at these sites[12,13], combined with that of the distribution of phosphate species in solution, suggest that the three regions of the phosphate sorption isotherm, each conforming to a Langmuir equation, may arise from three distinct phosphate sorption mechanisms at such sites.

This concept was tested by the change in negative charge during sorption of phosphate as measured by cation uptake. The difference (ΔNa) between the uptake of sodium by the sorbent during sorption of phosphate and that in controls containing the same initial sodium additions but no phosphate was determined. To facilitate the measurement of small changes in Na uptake in response to sorption of phosphate, a matrix solution of 10^{-4} M NaCl was used. Where applicable, phosphate was added as a solution of Na_2HPO_4 adjusted to *p*H 6.5. A 40-h sorption period was used. Sorption data obtained in this way are also represented by the same three distinct concentration ranges or regions, each conforming to a Langmuir equation. Values for *k* are comparable to those obtained for the equilibrium condition. This suggests that the non-equilibrium (40 h) condition is satisfactory within the scope of the experiment. Non-equilibrium *b* values for the Okaihau soil (Table 2), are however, considerably lower than equilibrium *b* values for the same soil (Table 1). This reflects the effect of the low ionic strength of 10^{-4} M NaCl on the rate at which equilibrium is attained[11].

Point A on the ΔNa phosphate sorbed curve (Fig. 1) for Okaihau soil and hydrous ferric oxide gel (Fe gel) corresponds approximately to the sorption maximum of region I. Point B corresponds to significant phosphate sorption in region III, and this is associated with an increase in ΔNa (Fig. 1, Table 2). Point C corresponds to continued sorption in region III.

Data in Fig. 1 and the ratio ΔNa:phosphate sorbed (Table 2), demonstrate that phosphate sorption in regions I and III involves an increase in the negative charge of the surface, whereas no change in surface charge occurs during sorption in region II (ΔNa is constant and ΔNa:phosphate = 0, based on sorption of phosphate in each region). The data also suggest that charge increases by approximately one equivalent per mole phosphate P sorbed in regions I and III. The somewhat lower value obtained for Okaihau soil in region I probably arises from the interference of cations, originally present in the soil, in charge balancing. This gives a lower uptake of added sodium at lower levels of phosphate sorption. Similar data have also been obtained for Egmont soil.

We suggest that the reaction mechanisms represented in equations (1), (2), and (3) below are responsible for sorption of phosphate in regions I, II, and III, respectively:

$$M-OH_2^{+}+H_2PO_4^{-} = M-H_2PO_4+H_2O \quad (1)$$
$$M-OH +H_2PO_4^{-} = M-H_2PO_4+OH^{-} \quad (2)$$
$$M-OH +HPO_4^{2-} = M-HPO_4^{-}+OH^{-} \quad (3)$$

The change in surface charge induced by each mechanism is in accord with changes in sodium uptake during phosphate sorption (Fig. 1, Table 2).

Additional evidence for these reaction mechanisms has been obtained from *p*H data and flocculation studies. During sorption of phosphate by Fe gel, *p*H increased rapidly beyond point A (Fig. 1, Table 2), corresponding to saturation of region I and significant sorption in region II (OH^- release; equation 2). Furthermore, a dramatic increase in the extent of flocculation of the Fe gel was also observed beyond point A (charge neutralisation; equation 1). Complete flocculation was maintained (zero charge increase; equation 2) until region III made a significant contribution to overall phosphate sorption (point B), when dispersion occurred (charge accumulation; equation 3).

Recent work in this laboratory (J. R. McLaughlin, personal communication) suggests that sorption of phosphate in regions I and II, corresponding to equations (1) and (2), results in the development of a "ferric phosphate-like" surface, and that sorption of phosphate in region III corresponds to sorption of phosphate as a potential determining ion at this surface. Such a mechanism would still result in unit increase in surface negative charge per mol phosphate sorbed in region III (Fig. 1, Table 2).

Although sorption of phosphate has previously been attributed to one or more of the mechanisms proposed above[6-10,14], this study represents the first quantitative evaluation of the relative importance of each mechanism over a wide solution phosphate concentration range. Our study extends the work recently reported by Rajan[12] in three distinct ways: first, sorption of phosphate by both soils and Fe gel has been studied in detail over a concentration range relevant to the soil solution; second, sorption has been studied at approximately the natural *p*H of the soil, covering the range of 4.6 to 8.1; and third, evidence for the mechanisms proposed has been obtained not only from charge and *p*H relationships, but also from an interpretation of sorption of phosphate based on the Langmuir equation.

Finally, our work also shows that a significant proportion of phosphate may be sorbed without increase in surface negative charge, a condition that has been implicit in the phosphate sorption mechanisms proposed by Hingston *et al.* [6-8].

Liquid crystals as lamellar reservoirs reduce thinning by drainage

FOAMS and thin liquid films have provided important model systems for theories of water–surfactant interactions in colloidal systems[1,2]. Particular interest has been focused on the stability and structure of black films, since they represent a theoretically attractive system with implications for both physical and biological sciences. Until now drainage studies of thin films have concerned films formed from dilute surfactant solutions, which are of limited stability (that is, with a lifetime of a few minutes).

Foams formed from aqueous solutions, in which a lyotropic liquid crystalline phase is present in equilibrium with a micellar surfactant solution, are of noticeably greater stability than foams formed from micellar solutions alone[3,4]. Two mechanisms have been suggested for this. First, the liquid crystalline phase may concentrate in the plateau borders and thereby reduce film thinning by drainage. Second, the liquid crystalline phase may act as a reserve for the components which comprise the foam lamellae, so that drainage thinning or thinning under mechanical deformation of the foam lamellae, which would otherwise occur, is counteracted[3]. We provide here the first direct experimental evidence of the second of these mechanisms in the stabilisation of films. Further, we show that a lyotropic liquid crystalline phase introduced mechanically into a foam formed from a micellar solution, spreads through a foam by way of the lamellae, and concentrates in the plateau borders.

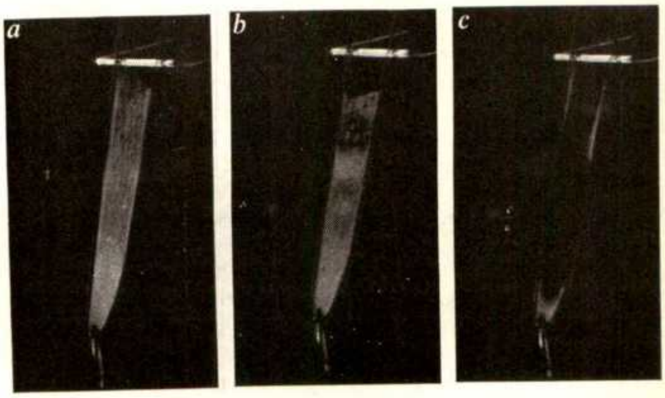

Fig. 1 Drainage of films formed from a micellar solution of 19% sodium caprylate, 7% decanol, 74% water, and stretched from 6 mm² to 100 mm². *a*, After 15 s; *b*, after 1 min. *c*, after 2 min. Film lifetime 150 ± 45 s. Film size 4 × 25 mm.

Films were drawn on a U-shaped glass frame (made from glass rod 0.5 mm in diameter) arranged so that the U opened upwards. The vertical arms of the U, separated by 4 mm, were closed by a horizontal glass barrier, which could be raised or lowered vertically to stretch the film.

The moveable horizontal glass barrier was set 4 mm above the base of the frame, and the frame was immersed in an aqueous solution. It was then removed, and any film that had formed (the area was 6 mm²) was immediately stretched, by moving the horizontal barrier out to an area of 100 mm². The lifetime of the film was measured, and drainage of the film was observed by watching the interference patterns produced by light incident at 45°. A micellar solution of 74% water, 19% sodium caprylate and 7% decanol was separated from a lamellar liquid crystalline phase of composition 38% water, 28% sodium caprylate and 34% decanol by the ultracentrifugation of a mixture of 70% water, 20% sodium caprylate and 10% decanol[5,6]. The micellar solution was used in the first film-forming experiments. The second series of film-forming experiments was carried out using the same micellar solution, but a 5 μl drop of the separated liquid crystalline phase was placed on the horizontal film barrier before immersion in the micellar solution.

The drainage of the film formed from the micellar solution alone is shown in Fig. 1*a*, *b* and *c* (after 15 s, 1 min and 2 min, respectively). The interference fringes initially present disappeared successively, and a black film formed from the top of the film downwards, extending to 5 mm below the upper barrier after 1 min, and becoming essentially complete after 2 min. A mean lifetime of 150 ± 45 s

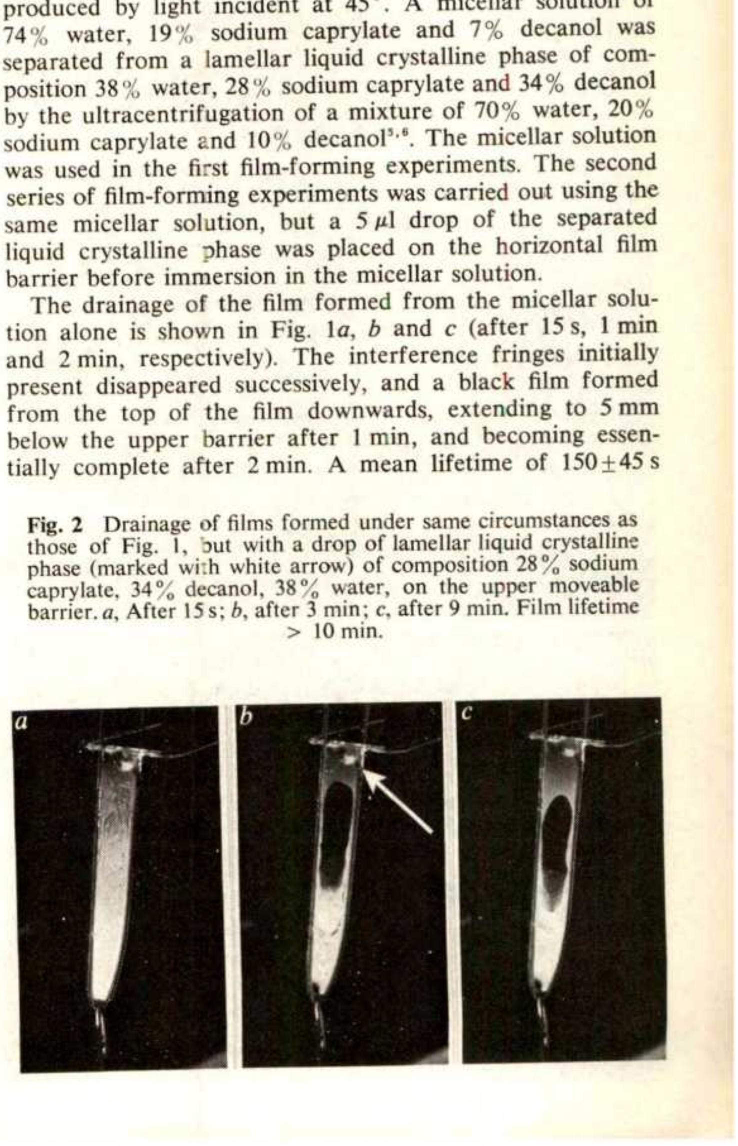

Fig. 2 Drainage of films formed under same circumstances as those of Fig. 1, but with a drop of lamellar liquid crystalline phase (marked with white arrow) of composition 28% sodium caprylate, 34% decanol, 38% water, on the upper moveable barrier. *a*, After 15 s; *b*, after 3 min; *c*, after 9 min. Film lifetime > 10 min.

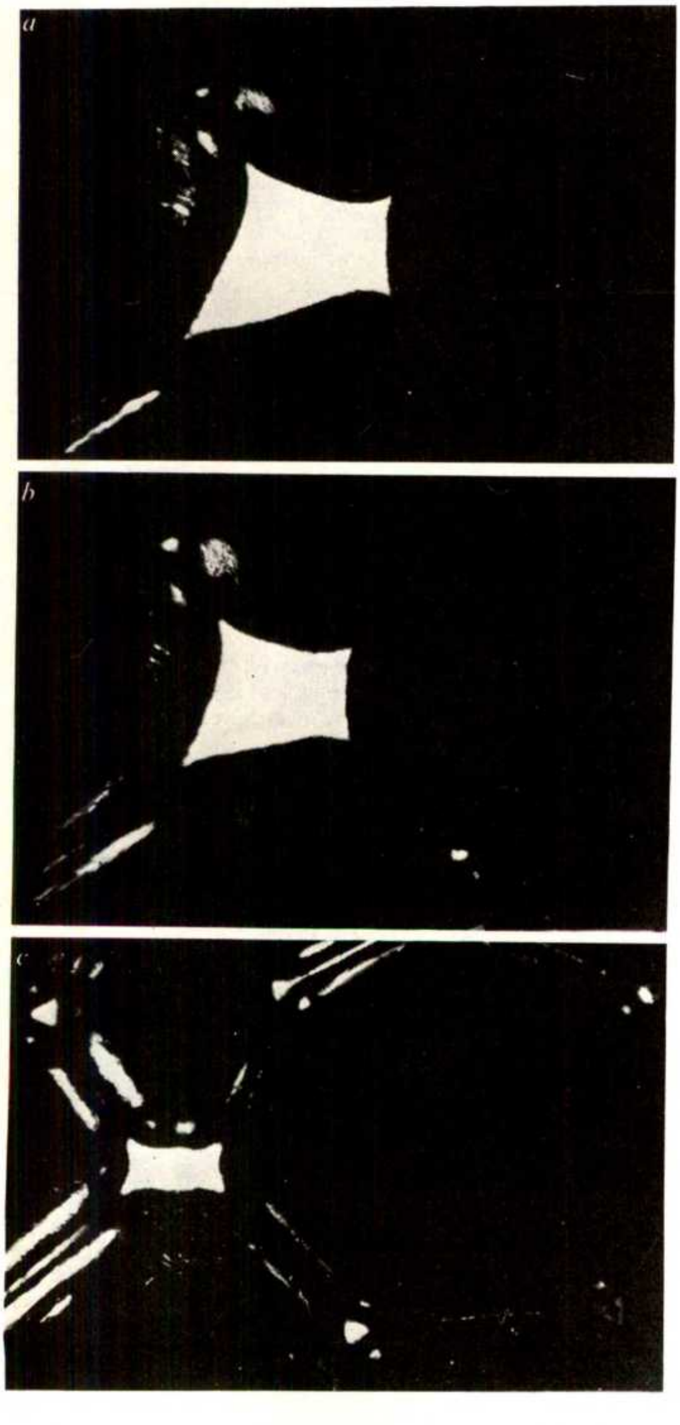
(mean deviation 14 s) was observed for the film. The drainage behaviour observed when a liquid crystalline phase was present on the upper film barrier is shown in Fig. 2*a*, *b* and *c* (after 15 s 3 min and 9 min, respectively). After 3 min, a black film had formed from 4 to 15 mm below the upper barrier, and below the black film interference patterns were observed. A silver film existed both above the black film and around it in the immediate neighbourhood of the glass frame. After 9 min, the black film region had decreased in size, and a silver film formed from the top downwards. The lower region of the film showed interference patterns, indicating a multilayer structure. When a liquid crystalline phase was present, film thinning was prevented, as is indicated both by the persistence of the interference patterns in the lower half of the film and by the spreading of a silver film over the black film in the neighbourhood of the liquid crystalline phase. The lifetimes of films formed in the presence of the lamellar liquid crystalline phase exceeded 10 min. These data demonstrate that the presence of a liquid crystalline phase in contact with a drawn film increases the film stability.

Fig. 3 Microphotographs (×30) of a foam formed from the micellar solution of the composition of the film shown in Fig. 1, to which a liquid crystalline phase, of composition given in Fig. 2, has been added mechanically at time $t = 0$. *a*, $t = 10$ s; *b*, $t = 3$ min; *c*, $t = 17$ min.



A foam was formed from a micellar solution of the composition already described, and observed in a 1-cm-thick cuvette with a polarising microscope. The foam initially contained no liquid crystalline phase and was only weakly birefringent. A drop (5 μl) of the liquid crystalline phase separated as described already, was placed mechanically in the foam using a fine platinum wire, and the system was observed visually. Photographic records in polarised light were made over a period of 17 min. The results are shown in Figs 3*a*, *b* and *c* (after 10 s, 3 min and 17 min, respectively). The liquid crystalline phase appears initially as a large, light region, which gradually shrinks. This phase was observed to spread into the foam lamellae, which become thicker and show stronger birefringence, and to concentrate in the plateau borders, which were observed as triangles of light of gradually increasing intensity.

The observations of films demonstrate that the spreading of a liquid crystalline phase over a film, to prevent drainage thinning[1,2], provides one mechanism for the stabilisation of films. The observations of foam show that a liquid crystalline phase concentrates in plateau borders, and can thus be distributed throughout a foam.

Comparison of associations of birth order with intelligence test score and height

No accepted genetic model can explain a true association of any human attribute with birth order. This view was not understood when Galton reported on the overrepresentation of firstborns among men of eminence. Recently, scientists have been intrigued with the possibility that studies of birth order may aid understanding of the environmental sources of differences in temperament and intelligence. Many such studies have been handicapped by the confounding effects of family size, which have been difficult to eliminate in spite of the application of a variety of techniques.

This paper examines the consistency of the association of birth order with adult intelligence test scores on the one hand and with adult height on the other. Test scores and height are associated attributes[1] that have been presumed to reflect certain common antecedents of development. Both test scores and height also relate to family size[2]. Our comparison of the association of intelligence test score and of height with birth order, while keeping family size constant, will help to separate antecedents of intellectual development from those of somatic development.

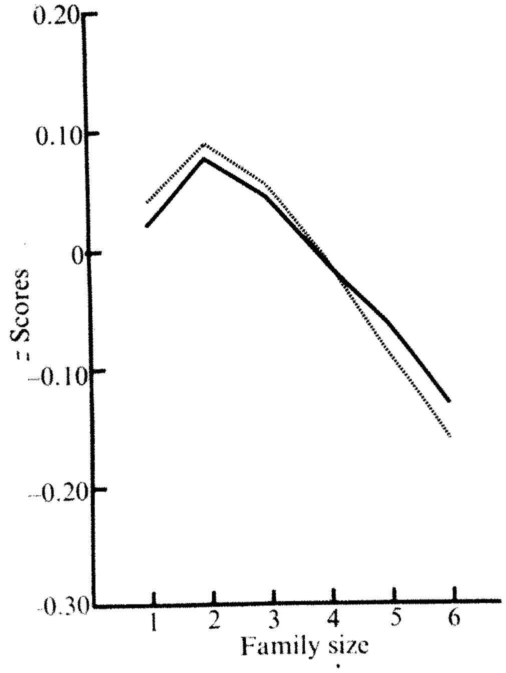
We have demonstrated[3] that birth order is related to intelligence test score and this relationship points to environmental effects, whether physical and biological, such as nutrition, or socio-psychological such as intra-familial socialisation. To distinguish between these two types of factors, we used height, which can be assumed to be related to physical and biological factors such as nutrition and childhood infections[4,5]. If height shows associations with birth order similar to those shown with intelligence test score, physical and biological hypotheses might best explain both. If, however, there is no association between birth order and height, then socio-psychological hypotheses may best explain the demonstrated variations of intelligence test score with birth order.

The data reported here consist of the coded records of the Dutch preinduction military examination for individuals born during 1944–46. These data are given in full elsewhere[6]. At 19, each young man is required to appear for an examination. The examination records were analysed with respect to class scores (1–6) on the Raven Progressive Matrices, information on birth order and family size, on father's occupation and on height.

The study population was incomplete in two respects. First, we excluded men from families containing more than seven children. Men who could show that three older brothers had served in the armed forces could claim exemption; by our estimates the loss of subjects by exemptions in families of less than seven was negligible. Second, some men were found incapable of taking the intelligence test (5.8%), and an additional 0.2% were not examined because they were either too short or too tall.

Figure 1 presents the contrast, in standardised normal deviates (z scores), for intelligence test score and height for all subjects grouped according to family size. The graph shows that family size is associated with both stature and test score—in general, individuals from smaller families are taller and brighter than those from larger families. Both height and test score in single-child families, however, are exceptions to this generalisation.

Fig. 1 Height (—) (cm) and intelligence (– – –) (Raven test score) by family size for the study population (n = 234,837).



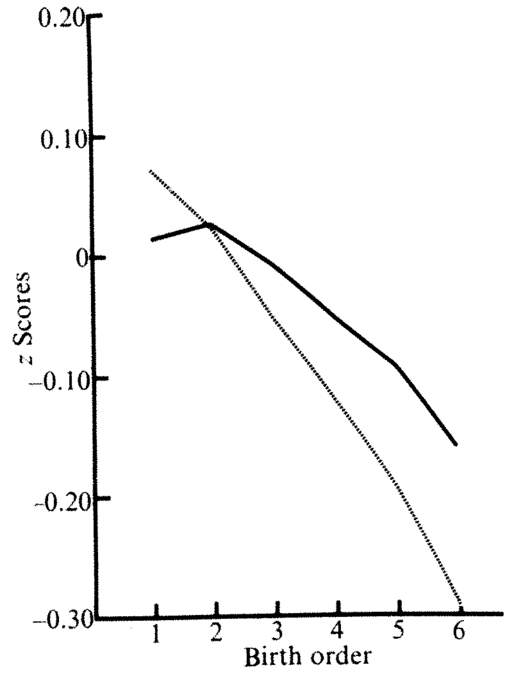


Fig. 2 Height (—) (cm) and intelligence (– – –) (Raven test score) by birth order for the study population (n = 234, 837).

Figure 2 contrasts the distributions for test score and height among all subjects by birth order. Intelligence test score and height present a configuration by birth order different from that for family size. The birth order gradient for intelligence test score shows the expected consistent decline from the first to the sixth birth rank. The gradient for height is less steep and the firstborn are shorter than the secondborn; a consistent decline in height for successive ranks begins only with the secondborn.

The z-score values for test score and height by birth order within each consecutive family size are shown in Fig. 3. Test scores show a consistent pattern for birth order, with the exception of only-child families. Within each family size, the firstborn always have higher test scores than the subsequent offspring. The regular declining gradient with successive birth orders is broken in only one instance, namely, the fourth child from five-child families. A stringent non-parametric test for discrepancy from ideal birth order[3] indicated that these results are statistically significant ($P < 0.001$).

The data for test scores also show a consistent pattern with regard to family size. For each birth order, members of small families have higher mean test scores than members of larger families, again excepting only-child families. There are two additional irregularities, at the second rank in three-child families and the fifth rank in six-child families. Family size effects on test scores are thus less consistent than birth order effects especially for birth rank five. Only earlier birth ranks meet the stringent requirements of our non-parametric test.

The values for height are quite dissimilar. There is no consistent relationship with birth order when family size is controlled. Actually, for two, three, and four-child families, there is a slight increase in height with increasing birth rank. In five and six-child families, the mean values are almost in a straight line. Thus, birth order effects with constant family size are not statistically significant. By contrast, height bears a consistent relationship with family size with constant birth order. With each successive increase in family size (except for single-child families) there is a consistent decline in mean height. The family size effects for height are statistically

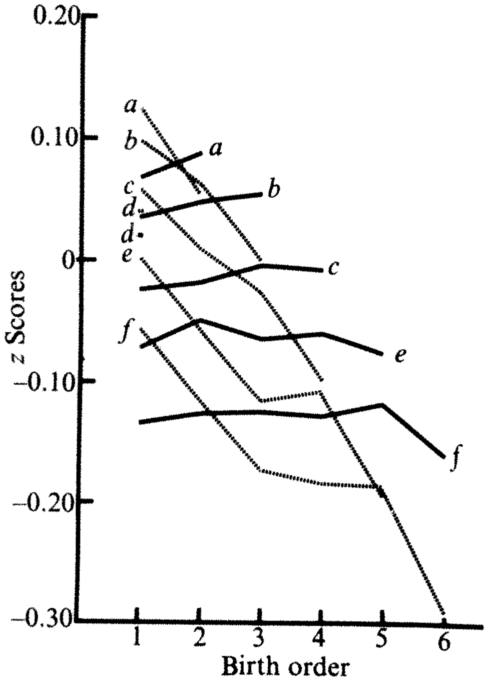

Fig. 3 Height (—) (cm) and intelligence (– – –) (Raven test score) by birth order within family size for the study population ($n = 234{,}837$). Family size: *a*, 2; *b*, 3; *c*, 4; *d*, 1; *e*, 5; *f*, 6.

significant ($P < 0.001$). Intelligence test score and height therefore diverge in relation to birth order.

Birth order and family size distributions for test scores and height were further analysed within social class. Social class was assigned according to father's occupation at the time of the son's military examination. Occupations were ordered into several occupational categories, but for convenience were finally reduced to only two classes: manual and non-manual. As expected, there were social class gradients for both test scores and height.

Social class does not explain either the test score or height gradients by birth order and family size. Among the manual social class the pattern for the total study population was replicated in all essentials for both test score and height. Among the non-manual class birth order effects for test score and for height also were similar to those for the total study population. Family size effects, however, were consistent for height but less consistent for test score: members of two, three, and four-child families scored higher than those of five and six-child families for given birth ranks, but within smaller sized families, family size effects were inconsistent and distinctly less marked.

The difference in the relationships of intelligence test score and height with family size and birth order indicates that the antecedents of the distributions of the two variables are not entirely shared. The association of test scores with birth order holds at virtually all levels of family size and social class, although the association with family size does not hold under all conditions. In contrast, the association of height with family size holds at all levels of birth order and social class, whereas the association with birth order disappears. The persisting birth order effects for test scores but not for height suggests that antecedents of adult intelligence are likely to stem from family environment and intrafamilial socialisation. Height is an index of the physical and biological environment during growth and its persistent relationship with family size is consistent with environmental effects. It seems, however, that the fullest development of intelligence requires more than nutritional adequacy and good physical health.

We thank the Department of Defence of the Netherlands for permission to use the preinduction examination data and acknowledge statistical consultation by Dr Janet Wittes, Assistant Professor, Hunter College, City University of New York. Experimental playbacks show vocal mediation of intergroup avoidance in a forest monkey

DISTINCTIVE vocalisations, audible over long distances, have been reported among many forest primate species, ranging from prosimians to apes[1-5]. Such loud calls have often been hypothesised to mediate territorial or other forms of spacing between conspecific groups, and indeed audibility over distances sufficient to serve in intergroup communication is one of their defining characteristics. Nevertheless, evidence in support of such hypotheses is primarily indirect (but see ref. 1), and investigation of the responses of animals to these calls is generally lacking.

I report here the response of gray-cheeked mangabeys, *Cercocebus albigena*, to playback of recorded vocalisations, made in conjunction with an observational study of this species in the Kibale Forest Reserve, western Uganda, between March 1972 and April 1973. The study took place in evergreen rain forest near the Kanyawara Forest Station (0° 34′N, 30°22′E), where human influence on the forest was minimal and there was no hunting of primates[6,7]. Mangabeys were found in spatially extended but socially cohesive groups of between 6 and 28 individuals, using home ranges several km^2 in extent[6,7].

Vocalisations were recorded from recognisable individuals using a Nagra III tape recorder and a Sennheiser MKH 804 directional microphone. Study concentrated on two habituated groups within which all individuals were recognisable. Records of responses to naturally occurring calls were kept during monthly periods when the mangabeys were followed systematically; playback experiments occurred outside those periods. Playbacks required two observers in radio contact, one to follow the test group and the second to operate the playback equipment. On each experimental day all movements and calls of group members were first noted during a control period of at least 30 min. A test vocalisation was then played back, using a Uher 4000 Report-L tape recorder and Kudelski DH external speaker, at approximately its normal intensity. Recording of movements and vocalisations was continued for at least the next 30 min. Because of the rapidity with which mangabeys were expected to habituate to such simulated encounters with other groups, several precautions were taken: only one experiment was conducted on a given day, and at least 2 d elapsed between any pair of tests; all calls were played back at least 75 m, and as much as 500 m, from the nearest mangabey; and, in each experiment, only a single call was played back to the test group. Thus mangabeys never witnessed the equipment in operation and in most cases never saw it at all. In these conditions, they gave

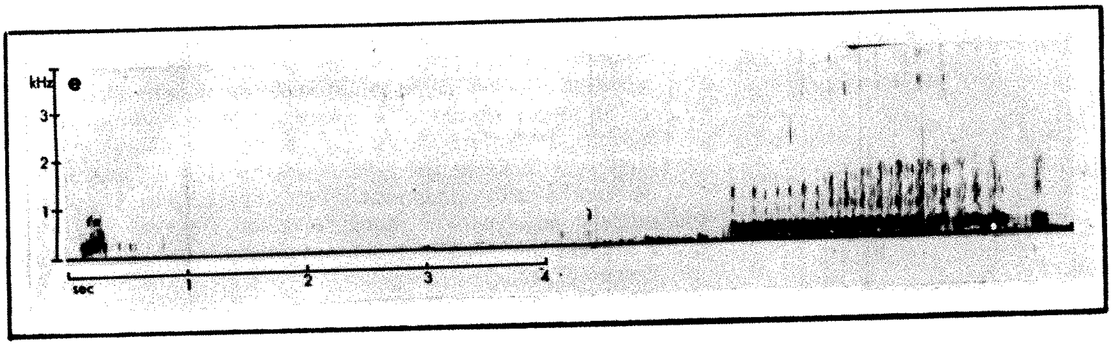

Fig. 1 Frequency-time display of whoopgobble call, analysed at double speed on Kay 6061B Sonagraph, wide band analysis; effective bandwidth, 150 Hz.

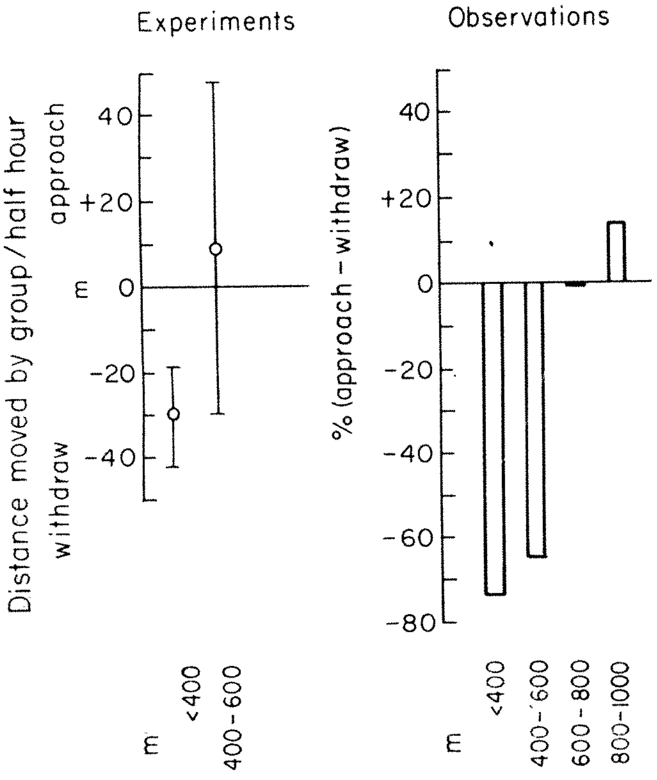
repeatable responses specific to both species and vocalisation.

The results reported here concern responses to the adult male vocalisations termed the 'whoopgobble' by Chalmers[8]. These calls consist of a low-frequency tonal whoop, then a 3–5 s pause, followed finally by a series of stacatto pulses comprising the gobble (Fig. 1). Because of their context and audibility, Chalmers suggested whoopgobbles 'might warn neighbouring groups of an occupied area'[8]. Playback experiments involved whoopgobbles recorded from known individuals in groups neighbouring or distant from the test group.

The response parameter most relevant to a possible intergroup spacing function is the net change in the movement of the groups as a whole after playback. Movements of the group centre of mass[6] during the 30 min preceding and succeeding the playback were compared and the group's net change in distance from the playback site was determined. The modal rate of group movement was 50–100 m per 30 min.

If a call is to maintain a minimal distance between groups, the response to playback of the call at less than this distance must be avoidance. More distant playbacks should be ignored or, conceivably, approached. Figure 2 compares the net changes in group movement in two series of experimental whoopgobble playbacks, one 'near' (100–200 m from the centre of the group, and more than 75 m from the nearest individual), the other 'distant' (400–600 m away). Changes in net group movement were consistent with the prediction. Near playbacks were never followed by group approach. Avoidance, on the other hand, was the exception in response to distant playbacks. The mean net displacement of the test group was away from near playbacks but slightly towards distant ones ($t = 2.68$, d.f. $= 13$, $P < 0.05$). Responses to naturally occurring whoopgobbles support the results of playback experiments. Whoopgobbles from a nearby group nearly always resulted in retreat within 30 min by the main study group, while those more than 600 m away did not (Fig. 2).

Fig. 2 Responses to whoopgobble calls near or distant from test group. Left, means and s. d. of net changes in group movement following playback; right, index of approach following naturally occurring calls. See text for further explanation. Sample sizes: (experiments) 7, 8; (observations) 19, 23, 7, 7, A slight but consistent difference in the distance from which playbacks and naturally occurring whoopgobbles were avoided may be due either to the playbacks possibly being quieter, and thus seemingly farther away, than naturally occurring calls; or to the fact that playback was from a height of about 2 m above ground, and was thus more highly attenuated than a call from the canopy.



To investigate the effect of the test group's location within its home range on its response to whoopgobbles, net changes in movement by the test group in its home range centre (defined as the central area which, during 1972–73, was occupied only by the test group) were compared with those in its home range periphery (the area which was occupied by other groups, as well as that test group). In an intergroup spacing system involving territorial defence, a spacing call heard nearby by the test group in its apparently exclusive area should be met with approach and (if the call is given by an intruding group rather than by playback equipment) displacement. On the other hand, if the call is heard near the extreme edge of the home range within an area of range overlap, withdrawal would be expected. Comparison of central and peripheral tests reveals no such trends. Net movement by the test group tended towards withdrawal in both cases and no significant differences appeared ($t = 0.47$, d.f. $=$ 13, $P \gg 0.05$). Again, responses to naturally occurring whoopgobbles parallel these results. When the main study group was in the centre of its own home range and the adjacent group trespassed deep into it, the main group still retreated after most whoopgobbles. The degree of retreat by the main group was not significantly greater ($P = 0.32$, one-tailed Fisher exact test) when the situation was reversed, with the main group trespassing near the heart of a neighbouring group's range.

Other responses which were both objectively measureable and clearly affected by playbacks included the spread of individuals within a group, the occurrence of immediate answering vocalisations, and the overall change in rate of whoopgobbles and other vocalisations by group members. Differences in these response measures, tests manipulating playback site rather than test group location, and observations of group movements and actual encounters all support the conclusion that response to whoopgobbles is a function of distance but not of position relative to the home range centre[6].

These results provide experimental support for the role of loud vocalisation in intergroup spacing, and indicate that playback techniques can be used successfully with free ranging primates. The unexpected finding that response does not vary with location indicates the more general value of playback techniques for investigating the pattern by which primate groups divide space among themselves, since the effects of such variables as identity

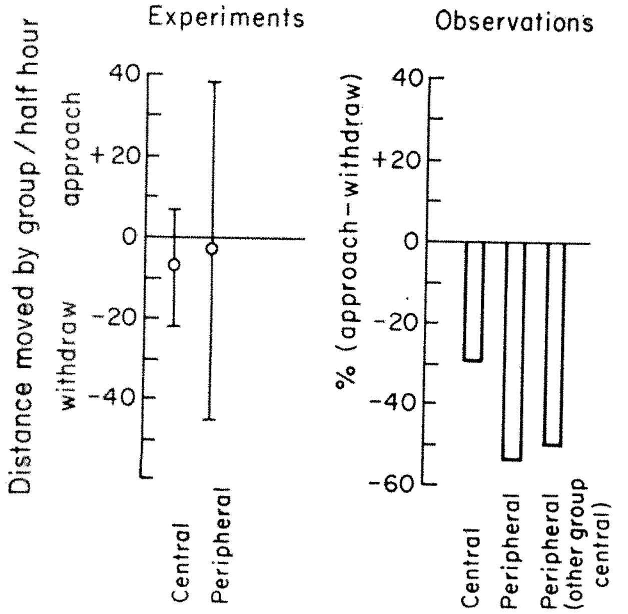


Fig. 3 Responses to whoopgobble calls when group is in the centre or periphery of its home range: comparison of experimental playbacks and naturally occurring calls. Conventions as in Fig. 2. Sample sizes: (experiments) 5, 10: (observations) 7, 30, 8.

of vocaliser, identity and size of vocalising groups, and level and location of resources can be investigated experimentally[6].

Dynamic complexity in predator-prey models framed in difference equations

THE complicated dynamics associated with simple first-order, nonlinear difference equations have received considerable attention (refs 1–4 and R. M. May and G. F. Oster, unpublished). In an ecological context, equations of this type provide a powerful and realistic means of modelling the behaviour of animal populations with non-overlapping generations, typified by many arthropods in temperate regions. May[4] has shown that such models, incorporating density dependence, have three regimes of dynamic solution in their parameter space, namely (1) a stable equilibrium point; (2) bifurcating cycles of period 2^n, $0<n<\infty$, where n is a positive integer and (3) behaviour which has been termed chaotic, that is, cycles of any integral period or complete aperiodicity, depending on the initial conditions. May[4] has indicated that such complexity can also occur in the wider context of competition between two species, described by two first-order, nonlinear difference equations of similar form to those governing single-species growth.

In this paper, we illustrate the dynamics of a predator–prey model for populations with non-overlapping generations and show that the model yields patterns of behaviour closely analogous to those observed in the first-order (single-species) situation. These may be compared with results on the type of solution possible in predator–prey models framed as differential equations, which guarantee for a large class of models the existence of either stable equilibria or stable limit cycles[5].

The model we chose to investigate is an extension of the familiar Nicholson–Bailey host-parasite equations[6], which purport to describe the interactions between a population of herbivorous arthropods and their insect parasitoids. The original model is unstable for all parameter values[7]. Our extension, which eliminates this unrealistic behaviour, involves the inclusion of density-dependent self-regulation by the prey. The equations of the model are:

$$\begin{aligned} H_{t+1} &= H_t \exp[r(1 - H_t/K) - aP_t] \\ P_{t+1} &= \alpha H_t[1 - \exp(-aP_t)] \end{aligned} \qquad (1)$$

The self-regulation of the prey in the absence of predators has already been documented by May[4], with a stable equilibrium point for $0<r<2$, bifurcating cycles for $2<r<2.692$ and chaos for $2.692<r$. The choice of an identical form of density dependence in a predator–prey model therefore enables us to compare the parameter values at which chaotic behaviour ensues, and hence indicate whether the introduction of a predator makes the onset of chaotic behaviour more or less likely.

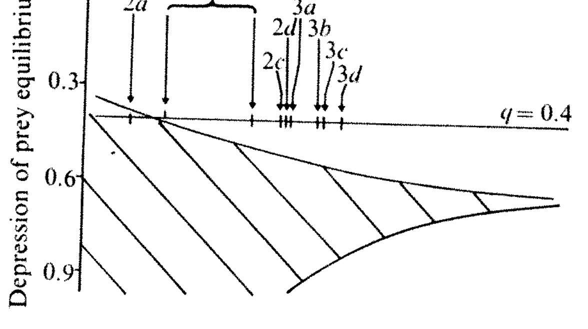
Analysis of the local stability properties of the model was performed using the method of Beddington[8]. The conditions for stability were found to depend on whether the roots of the equation

$$\begin{aligned} &\lambda^2 - \lambda(1 - r + \varphi) + (1 - rq)\varphi + r^2q(1 - q) = 0 \\ \text{where} \quad &\varphi = r(1 - q)/\{1 - \exp[-r(1 - q)]\} \end{aligned} \qquad (2)$$

lay within the unit circle. The parameter q is defined as the equilibrium prey population density, H^*, divided by the carrying capacity K; q is therefore a measure of the extent to which the predator can depress the prey below its carrying capacity. Application of the Schur-Cohn criteria[9] to equation (2) yields the demarcation of stable from unstable parameter space: this is illustrated in Fig. 1. Extensive numerical investigations within the domain of stable parameter space indicate that the equilibrium point is globally stable, although a Lyapunov function for the system has not been constructed.

Before considering the non-equilibrium behaviour of the model, we digress to point out the difficulties involved in recognising complicated dynamic behaviour in second-order models. *A priori*, we would expect limit cycles of integer period to be rare; it is more likely that the periods of any limit cycles that do exist will be predominantly non-integral, or indeed

Fig. 1 Stability boundaries for the predator–prey model, equation (1). The equilibrium point is stable inside the hatched area only. Simulations for the points marked on the transect $q = 0.4$ are illustrated in Figs 2 and 3.



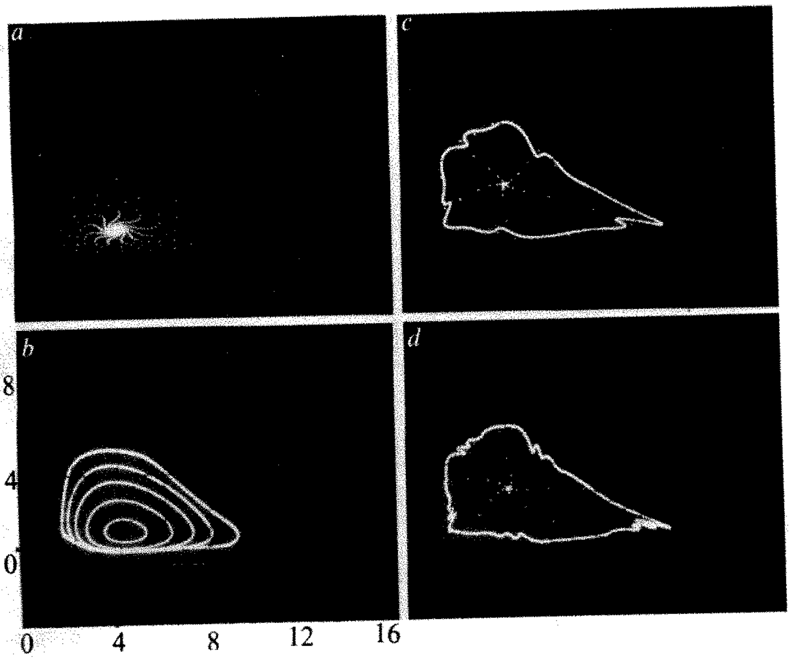


Fig. 2*a*, The realised trajectory for the model in the domain of oscillatorily stable parameter space $r = 0.5$, initial densities $H_0 = 8.6$, $P_0 = 1.1$. The plot indicates the time path followed to the equilibrium point. $q = 0.4$, $a = 1$, $K = 10$ throughout Figs 2 and 3. All plots are shown to the same scale. *b*, A succession of closed trajectories, realised after varying time periods from the initial point $H_0 = 3$, $P_0 = 3$. The parameter values, moving outward from the smallest curve, are (1) $r = 0.75$, (2) $r = 0.9$, (3) $r = 1.1$, (4) $r = 1.35$, (5) $r = 1.8$. Simulations indicated that the populations homed in on the closed curve trajectories from all regions of phase space. *c*, The realised trajectory of the model with $r = 2.1$ and initial densities close to equilibrium. The final closed curve is substantially different from the family of curves illustrated in *b*. *d*, as *c* with $r = 2.15$. The closed curve has now developed five kinked areas where the population points occur more frequently. Ordinates and abscissae are H_t and P_t respectively.

irrational. Correspondingly, limit cycles will be extremely difficult to detect simply by viewing the trajectory of one or both populations as a function of time. At most, this will permit a distinction only between integer cycles and other behaviour. In general, we would expect the existence of limit cycles in second-order models to be characterised by the populations following closed trajectories in phase space. We have performed our numerical simulations with this in mind: the non-equilibrium behaviour of the model was investigated by plotting the realised trajectory in phase space, using a storage oscilloscope on line to a computer.

The results of the simulations are presented in the context of a transect in parameter space (Fig. 1). The various types of behaviour of the model, corresponding to points on the transect, are illustrated in Figs 2 and 3. An initially stable point is succeeded by a hierarchy of stable limit cycles of increasing, non-integral period and increasing complexity, ultimately breaking down to cycles of integral period k (where $k = 5$), which then bifurcate to cycles of period $2k, 4k, \ldots, 2^n k$. These are followed by a regime of complex, but bounded, behaviour consisting either of limit cycles of high integral period ($2^n k > 10{,}000$) or of aperiodic chaos. The implications of the model in other zones of parameter space will be discussed elsewhere. The most important difference in these regions hinges on the basic period, k, of the integer cycles. Clearly, when compared with May's[4] results for a single-species model, the introduction of a predator has produced qualitatively new behaviour.

In the particular example illustrated predation has resulted in chaotic or high period limit cyclic behaviour for values of the prey growth rate parameter r only slightly below that in the single-species case. For other values of the parameter q however, we find that the onset of chaos occurs at values of r both significantly below (for example, $q = 0.30$, $r \approx 2.1$) and significantly above (for example, $q = 0.50$, $r \approx 3.3$) that of the single-species case ($r = 2.692$). A rough characterisation of what is obviously a somewhat complicated relationship is that the further the predator depresses the prey below its carrying capacity, the lower is the growth rate required for chaos. As a caveat, we note that the introduction of thresholds into population models (for example, an Allee[10] effect) will necessarily exclude the high amplitude limit cycles and larger chaotic domains. Nevertheless, our preliminary studies suggest that models incorporating such thresholds display effectively similar patterns of behaviour.

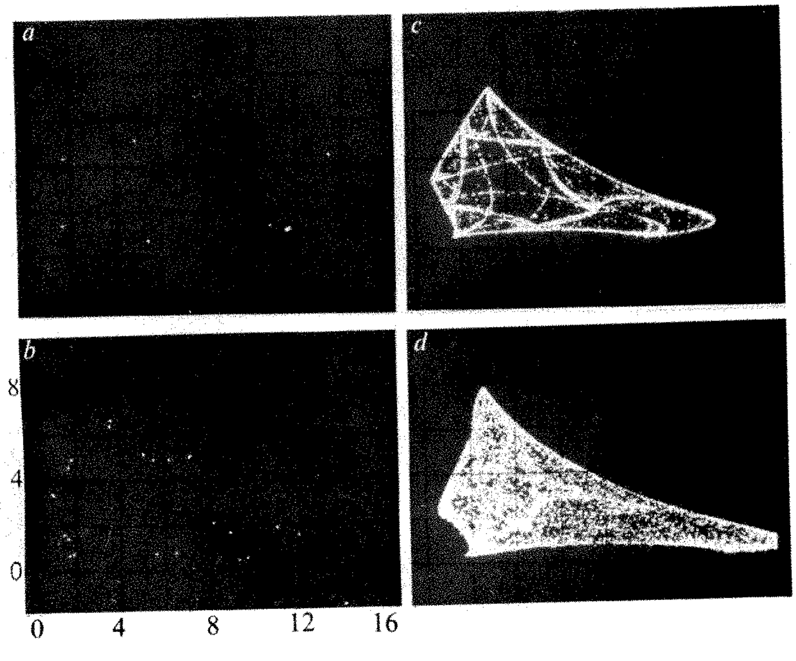

Fig. 3 *a* and *b*, Point limit cycles of period 5 and 20 realised after 100 iterations of the model from an initial point. Parameter values: (*a*) $r = 2.2$;(*b*) $r = 2.488$. Between these two points in parameter space lies a domain of stable ten-point cycles and for $r > 2.488$ cycles of period 40, 80 . . . have been found. *c* and *d*, Realisation of 10,000 points from the population trajectory started at initial densities $H_0 = 3$, $P_0 = 3$. *c*, $r = 2.55$. The structured, bounded figure shown possesses well defined areas where no points appear for iterations > 100,000. *d*, $r = 2.75$. Increased numbers of iterations yield a dense cover over the whole figure, within the limits of the oscilloscope resolution. Ordinates and abscissae are H_t and P_t respectively.

The existence of high period cycles or chaotic behaviour in predator-prey models (the distinction is unimportant for practical purposes) may be of considerable importance in interpreting the patterns of fluctuation shown by many arthropod populations in the field, as this implies the possibility of long term coexistence between predator and prey within well defined limits, but of a seemingly random nature. The temptation to ascribe such behaviour to 'environmental fluctuation' is obvious. Thus a recognition that such behaviour may occur in an extremely simple, entirely deterministic predator-prey model is of considerable importance.

We thank Professor Robert May for discussions.

Prey death rates and rate of increase of arthropod predator populations

CENTRAL to our understanding of predator–prey dynamics is the relationship between the death rate imposed on the prey by the predators and the rate of increase, or numerical response, of the predator population. Most of the familiar mathematical models of predator–prey systems involve the assumption that there is a simple linear relationship between the number of prey killed and predator reproduction[1–4]. Although this assumption is valid for most insect host–parasitoid systems[2], the rate of increase of other predatory arthropods is a more complex function of the prey consumed. For successful reproduction, each instar must find and eat several prey to complete development. Thus the predator rate of increase will depend on the duration of, and the survival rate within each instar and the fecundity of the adults. Where models for the predator rate of increase have incorporated more complex nonlinear relationships[5,6], these relationships are of too abstract a character to allow simple experimental corroboration or refutation. In this paper we propose models that characterise the effect of prey consumption on the components of the predator rate of increase that are specifically designed to relate our hypotheses to field or laboratory data.

Much of the data available for testing these models comes from experiments in which a number of predators are exposed to a variety of prey densities. Thus it is necessary to utilise an expression for the number of prey attacked in terms of prey density N and predator density P. Indeed this is ultimately the form in which population models are likely to be framed. An instantaneous form for the number of prey attacked per predator, N_a, in time T assuming random search and random distribution of prey is, with unit area

$$N_a = aNT/[1+aT_hN+bT_w(P-1)] \qquad (1)$$

where a defines the rate of encounters between predators and prey, T_h is the handling time, b the encounter rate between predators and T_w the time wasted on an encounter between predators[7]. In many cases the assumptions of random search and random prey distribution are invalid[2,8] and in these situations a and b will be functions of the relative distribution of predator and prey.

For simplicity, and because this is the most usual type of experimental design, we explore the relationship between the prey death rate defined by equation (1) and the predator rate of increase for a single predator confronting a variety of prey densities. This simplifies equation (1) to

$$N_a = aNT/(1+aT_hN) \qquad (2)$$

the well known 'disc equation' of Holling[9,10].

Energetic considerations demand that a predator must allocate at least some food for maintenance. Accordingly this determines a threshold below which growth will not take place and eggs will not be produced. The growth rate of a predator g and the fecundity F will therefore be related to the energy intake I from food consumption by essentially similar models; thus

$$g = \delta(I-c) \qquad (3)$$

$$F = \lambda(I-c) \qquad (4)$$

where c is a constant determined by the maintenance energy

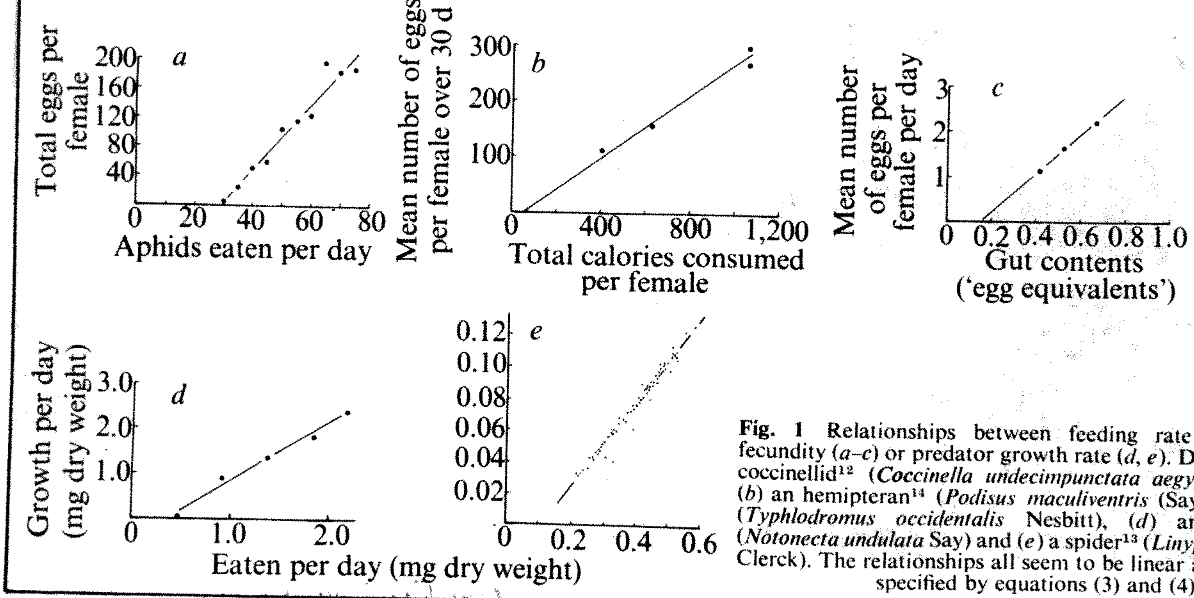

Fig. 1 Relationships between feeding rate and predator fecundity (*a*–*c*) or predator growth rate (*d*, *e*). Data are for (*a*) a coccinellid[12] (*Coccinella undecimpunctata aegyptiaca* Reiche), (*b*) an hemipteran[14] (*Podisus maculiventris* (Say)), (*c*) a mite[16] (*Typhlodromus occidentalis* Nesbitt), (*d*) an hemipteran[17] (*Notonecta undulata* Say) and (*e*) a spider[13] (*Linyphia triangularis* Clerck). The relationships all seem to be linear and of the form specified by equations (3) and (4).

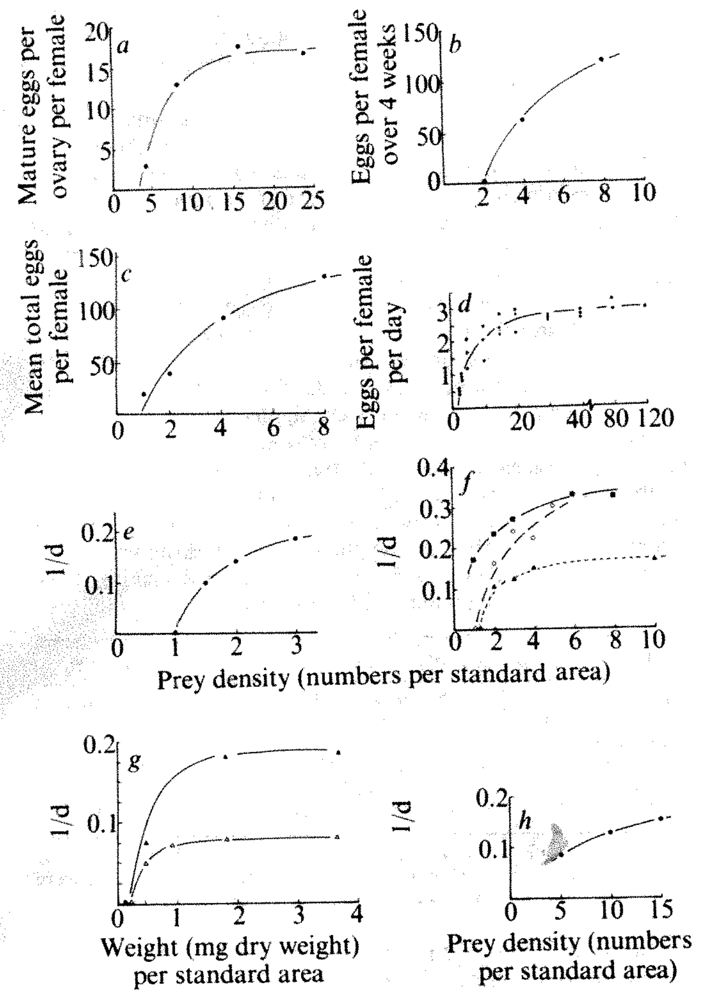

Fig. 2 Relationships between prey density and predator fecundity (*a–d*) or development rate (*e–h*). Data are for coccinellids (*a*, *e*) *Adalia decempuntata* (L.)[18] and (*f*) *Adalia bipunctata* (L.)[19]; hemiptera (*b*, *g*) *Notonecta undulata*[17] and (*c*) *Anthocoris confusus* Reuter[20]; and mites (*d*) *Phytoseuilus persimilis* Athias-Henriot[21] and (*h*) *Melichares dentriticus* (Berl.)[22]. All the relationships take the form of a negatively accelerating rise to a plateau, as predicted by equations (8) and (9), with positive intercepts on the prey-density axis. ■, Instar I; ○, instar II; ▲, instar IV; △, instar V.

requirements of the instar and the proportion of ingested food assimilated and δ and λ are appropriate proportionately constants (Fig. 1). The duration of an instar d can now be simply related to the growth rate by the observation that if W is the necessary weight gain within the instar, then the ratio W/g defines d, and the inverse of d the development rate. From equation (3) it follows that

$$1/d = (\delta/W)\,(I-c) \tag{5}$$

One important complication occurs when predators with a restricted food supply moult to the next instar at lower body weights than individuals with an abundant food supply[11,12], in extreme cases with a body weight below that at which they entered the current instar[13]. Nevertheless, the data available for organisms which exhibit this phenomenon can still be described by an equation of the same essential structure as equation (5)[13,14]

$$1/d = \alpha(I-\beta) \tag{6}$$

In this case however the constants α and β have no simple biological interpretation.

It now remains for us to relate both development rate and fecundity to prey density. Clearly the rate of ingestion I will be approximately proportional to the number of prey eaten. Thus as an approximation

$$I = kN_a \tag{7}$$

where k is the appropriate proportionately constant determined by the biomass of prey and the fraction of each prey killed that is utilised. We now use our simplified expression (2) to arrive at relationships for a single predator between fecundity and prey density and instar duration and prey density:

$$F = \lambda[kaN/(1+aT_hN)-c] \tag{8}$$

and

$$1/d = \alpha[kaN/(1+aT_hN)-\beta] \tag{9}$$

These relationships are supported by a variety of data (Fig. 2).

Ignoring mortality from other causes, if the frequency with which members of a population of predators die is normally distributed about a mean ingestion level μ_I with standard deviation σ_I (ref. 15), the proportion of the population surviving, s, to complete development within any particular instar at an ingestion rate I will be given by

$$s = 1/2\pi\int_{-\infty}^{z}\exp(-z^2/2)\mathrm{d}z \tag{10}$$

and

$$z = (I-\mu_I)/\sigma_I \tag{11}$$

It is now possible to utilise equations (2) and (7) and express s in terms of prey density N. Some possible relationships generated by this derived expression are illustrated in Fig. 3, which can be compared with the experimental data in Fig. 4.

Clearly any model which incorporates the same essential features as our equations (a threshold, and a saturation at high prey density) is likely to imply qualitatively similar relationships to those illustrated in Figs 2–4. Our aim has been, however, to develop models the parameters of which may be estimated experimentally and in which the underlying biological mechanisms are made explicit.

Fig. 3 Hypothetical relationships between (*a*) the proportion of individual predators surviving to the end of an instar and their mean feeding rates during that instar, and (*b*) predator feeding rates and prey density; the former is defined by equation (10), the latter by equation (2), for various values of a and T_h. The asymptotic rates of feeding defined by curves (i) and (ii) in (*b*) are just sufficient to lead to maximal survival in (*a*). Combining curve (*a*) with the curves shown in (*b*) produces (*c*), which relates survival to prey density. The hypothetical relationships in (*c*) should be compared with the experimentally derived curves shown in Fig. 4.

SCIENCE COLLEGE

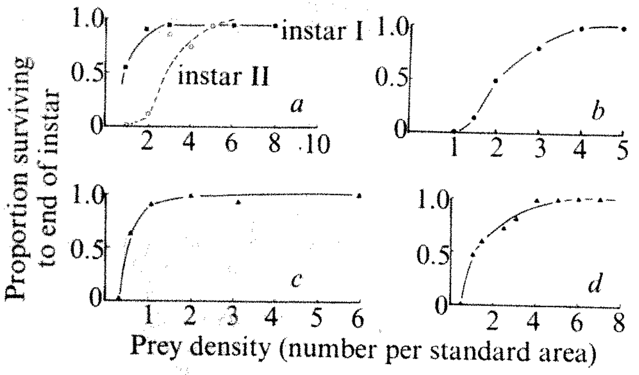

Fig. 4 Relationships between mean prey density during an instar and the proportion of individual predators surviving to the end of that instar. Data are for (*a*, *b*) coccinellids[18,23] (*Adalia decempunctata*, and *Adalia bipunctata*), (*c*) an hemipteran[15] (*Blepharidopterus angulatus* (Fall.) and (*d*) a spider[13] (*Linyphia triangularis*). ■, Instar I; ○, instar II.

Having documented well-corroborated relationships between the components of the predator rate of increase and the prey death rate, the task remains to investigate their implications for the behaviour of predator-prey systems. These problems, together with a more detailed treatment of the material in this paper, will be discussed elsewhere.

Polymorphism of erythrocyte potassium concentration in seaweed-eating sheep

INDIVIDUAL normal adult sheep have either a high or low erythrocyte potassium concentration, determined genetically by a simple allelic pair in which the gene for low K is dominant. High potassium (HK) animals have low erythrocyte sodium and low potassium (LK) animals high. Both phenotypes are present, and in all proportions, in 115 of 129 populations listed[1].

It is tempting to expect that such a striking physiological distinction would have a clear adaptive significance in an environment that offered an appropriate selection pressure. North Ronaldsay seems to be such an environment. The primitive native sheep of this small island in Orkney have been confined by a wall to the sea-shore for at least 140 years. Their diet is almost entirely of fresh seaweed and it is presumed that their intake of sea-salt is unavoidably high. These sheep number approximately 4,500 (ref. 2).

Blood samples were taken on the island from 113 adult sheep; 5 were HK and the rest LK. The average plasma sodium and potassium concentrations of the LK sheep were found to be about the same as those of LK mainland sheep, but the estimates for erythrocyte concentrations were significantly lower.

The diet of the Orkney sheep therefore does not seem to have affected plasma electrolyte levels, but the reduced values for the erythrocytes implies that the factors maintaining the electrolyte gradient across the erythrocyte membrane differ from those in mainland sheep. Although one phenotype is thus shown to have been modified, the exigencies of life on North Ronaldsay have not overwhelmingly favoured either phenotype.

Table 1 Blood electrolyte estimates for LK sheep, (mEq l^{-1})

Origin	North Ronaldsay	Scottish mainland
Number of sheep	108	314
Plasma Na	133.5 ± (0.51)	136.3 ± (0.32)
Plasma K	5.0 ± (0.05)	5.1 ± (0.04)
Erythrocyte Na	59.7 ± (1.44)	70.9 ± (0.94)
Erythrocyte K	9.8 ± (0.26)	19.9 ± (0.27)

Arithmetic means (s. e.) for North Ronaldsay sheep. Adjusted means ± s. e. for Scottish mainland sheep. (Values for the latter were calculated from the data of reference[3] by Mr E. A. Hunter.)

Our conclusion is that if there were any ecological significance in the polymorphism of blood electrolyte concentrations it remains obscure. A detailed account will be given elsewhere.

The authors acknowledge financial assistance from Trinity College, Cambridge and from the ARC. We thank the people of North Ronaldsay, in particular Mr R. J. Swanney and the North Ronaldsay Sheep Court, without whose enthusiasm and hospitality this study could not have been undertaken.

Antibody-induced cell-mediated damage to human endothelial cells *in vitro*

THE blood vessels of allografted organs are important sites for immunological injury[1–3]. *In vivo*, this is thought to be the result of interactions between antigenic determinants on donor vessel endothelium and recipient immunocompetent cells and antibodies. *In vitro*, damage to cultured pig endothelium by cytotoxic xeno- and alloantisera in the presence of rabbit complement has previously been described[4]. In addition, both canine[5] and human[6] endothelial cells are capable of stimulating allogeneic lymphocytes to blastogenesis and DNA synthesis, thus demonstrating the ability of endothelium to initiate directly an immunoproliferative response *in vitro*.

Antibody-induced cell-mediated cytotoxicity (AICC) has been reported previously, using a variety of allo- or xenogeneic target cells[7–9] and could be an important *in vivo* mechanism in the rejection of allografts. Here we describe damage to ^{51}Cr-labelled dissociated human endothelial cells *in vitro* by non-immune allogeneic lymphoid cells in the presence of anti-HL-A antibodies.

Endothelial cells were isolated from the vein of human umbilical cords by collagenase digestion, using a modification of the method described by Jaffe *et al.*[10–11]. Those cells were identified as endothelial in nature by light and electron microscopy, by their possession of typical inclusion bodies, by their typical growth pattern in culture and by their ability to stimulate allogeneic lymphocytes (for details see ref. 6). Neonatal lymphocytes (autologous to the endothelial cells) were separated from heparinised cord blood by Ficoll–Isopaque flotation. A small portion of the lymphocytes, approximately 0.1×10^6 cells was used to type the endothelial cell donor for HL-A, using the standard micro-lymphocytotoxicity test[12]. Both endothelial cells and lymphocytes were labelled with ^{51}Cr sodium chromate (Na_2CrO_4, Institutt for Atomic Energy, Kjeller, Norway) by incubating approximately 0.5×10^6 cells in 1 ml of culture medium containing 200–300 µCi ^{51}Cr for 90 min. The endothelial cells were usually more heavily labelled than the lymphocytes. The labelled cells were washed and filtered through sterile gauze before resuspension.

The anti-HL-A antisera used in each test were obtained from the battery of typing sera used in this laboratory for routine HL-A typing. The particular antiserum selected for each experiment had a specificity for at least one of the HL-A antigens possessed by the endothelial cell donor. The antisera were inactivated by heat (56 °C for 30 min) and diluted in foetal bovine serum (FBS). The basis for the selection of effector cell donors from previously non-alloimmunised individuals was a non-reaction with the particular HL-A antiserum used in each test. Peripheral blood lymphocytes were separated from these donors by Ficoll–Isopaque flotation. The AICC test is described in the legend to Fig. 1 (see also ref. 13).

The influence of the concentration of anti-HL-A antisera on the isotope release (endothelial cell cytolysis) is shown in Fig. 1. Release of ^{51}Cr from lymphoid target cells separated from cord blood of the endothelial cell donor is also shown for comparison. Incubating the labelled endothelial cells, either with heat-inactivated antiserum in the absence of effector cells, or with effector cells in FBS, always resulted in a lower isotope release than that observed by incubating the cells alone in FBS. In the presence of both antiserum and effector cells, a significant release of isotope was obtained for endothelial as well as lymphoid target cells in all five of the combinations tested. This was the case even at an effector–target cell ratio of 10:1. Increasing the number of effector cells fivefold, resulted in a relatively small increase in isotope release (approximately 25%). One of the antisera tested (anti-HL-A12) gave an isotope release of endothelial cell targets of approximately 35% at a dilution of 1:1,000. At this dilution, the percentage release for lymphoid cell targets was only 9%.

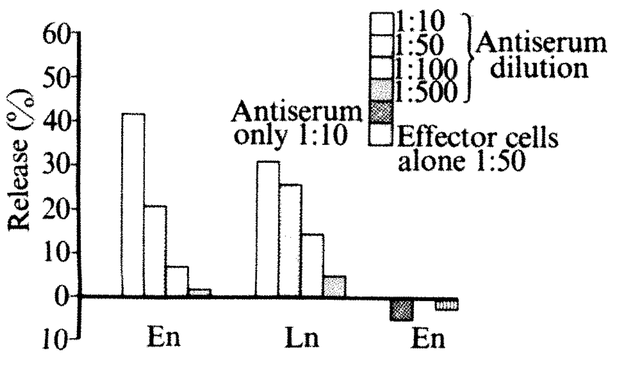

Fig. 1 2×10^3 ^{51}Cr labelled endothelial cells (En) or lymphocytes (Ln) were incubated for 18 h in the presence of 1×10^5 peripheral blood lymphocytes and various concentrations of an anti-HL-A3 antiserum diluted in FBS. All experiments were carried out in triplicate in the wells of round-bottomed microtitre plates in a total culture volume of 0.2 ml. Assay for ^{51}Cr release was carried out by transferring 0.1 ml of the cell supernatant to counting vials containing 4 ml of scintillation fluid (Insta-Gel) and counting in a liquid scintillation counter. The percentage release was calculated using the median of each triplicate culture from the expression:

$$\frac{\text{Experimental c.p.m.} - \text{Spontaneous c.p.m. in FBS}}{\text{Max. c.p.m. in Cetavelon} - \text{Spontaneous c.p.m. in FBS}} \times 100$$

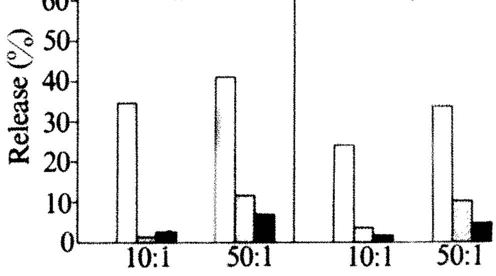

Fig. 2 The percentage release in AICC for labelled En (*a*) or Ln (*b*) target cells (□) in the presence of five times as many unlabelled En (////) or Ln (■) bystander cells. Effector–target ratio 10:1 or 50:1 as shown. Antisera (anti-HL-A12) dilution; 1:100. En and Ln target or bystander cells were obtained from the same donor. The experimental procedure was otherwise as explained for Fig. 1.

To determine if the cytolytic mechanism towards endothelial cells was similar to that operating towards lymphoid target cells in AICC, we investigated the effects of adding an excess of unlabelled target-autologous bystander lymphoid or endothelial cells to the targets under test. The results are shown in Fig. 2. At an effector–target ratio of 10:1, the addition of either five times as many unlabelled bystander endothelial or lymphoid cells to the labelled endothelial target cells clearly inhibited the release of isotope. Increasing the ratio to 50:1, in the presence of bystander cells, increased the lysis of target cells (compared with that for a ratio of 10:1), but did not completely compensate for the presence of unlabelled cells. In these experiments, increasing the number of effector cells always resulted in an increased isotope release. Therefore, the inhibition observed when unlabelled target-autologous bystander cells were added to the cultures, could not be caused primarily by an increased number of cells *per se*. Similar results were obtained in experiments using labelled lymphoid cells as target cells (Fig. 2*b*), where either adding unlabelled lymphocytes or endothelial cells greatly reduced the ^{51}Cr release otherwise observed.

These results indicate that human endothelial cells can be damaged by non-immune peripheral blood lymphocytes in the presence of anti-HL-A antibodies, even at rather low antibody concentrations. Complement-dependent cytotoxicity towards dissociated endothelial cells of both dog and pig, in the presence of cytotoxic allo- or xenoantiserum, has been reported previously[4,14]. In these experiments, high antibody concentration, as well as the presence of xenogeneic complement, was necessary to demonstrate cytolysis of the endothelial cells. All of the antisera used in our experiments were heat inactivated, and therefore the effects observed were by necessity complement independent.

Previous studies have indicated that the target structures on lymphoid cells in AICC are most likely the serologically defined HL-A antigens[9,13,15], although other interpretations cannot be ruled out. Our results imply that both endothelial and lymphoid target cells compete for the same cytotoxic effector mechanism (competitive inhibition, Fig. 2) in AICC. This suggests an apparent similarity or identity between the target structures on endothelium and lymphocytes; by inference possibly the HL-A antigens found on all human cell types tested so far[12] including endothelium[16]. On the other hand, specific cytotoxic xenoantisera for canine endothelium have been reported[17] suggesting the existence of antigenic sites on endothelium not found on lymphocytes from the same donor. Similar differentiation antigens on human endothelial cells and the possibility that these specific structures can also serve as targets in AICC, are now under investigation.

T & B lymphocytes in thymus of SJL/J mice

The thymus reaches relative maximal development early in life followed by apparent programmed involution, which is eventually expressed in reduced functions of the T cell system. In the SJL/J mice we observed an interesting deviation of the normal thymus pattern, namely a secondary increase in thymus weight from the age of 7–9 months onwards (average weight of 2-month-old thymus being 60 mg compared with 130 mg in a 14-month-old normal mouse). The timing of this secondary thymus weight increase seems to coincide with the comparatively early, age-related, progressive decrease in the immuneresponsiveness of SJL/J mice described recently[1]. We therefore investigated the thymus population pattern in SJL/J mice in relation to age increase, using membranal antigenic markers as well as functional criteria. Based on antigenic properties of the cell surface of mouse thymocytes, the thymus population can be divided into two defined subpopulations. The major population (about 85%), which resides mainly in the cortex, possesses high levels of θ antigen and low levels of surface H-2 alloantigens. The remaining minor population has antigenic properties similar to peripheral T cells, namely low levels of θ and high levels of H-2 (refs 2 and 3). The immunological reactivity is usually attributed to the small, high H-2 subpopulation[4]. Thymocytes belonging to the B cell compartment are rarely found[5].

In this study, the presence of θ antigen and high levels of H-2 alloantigen on thymocytes was determined using a cytotoxic test. From the age of 4 months onwards a decrease in the percentage of θ-bearing cells could be detected in the thymus of SJL/J mice. The decrease was progressive with increasing age, namely 85% at the age of 1–2 months to about 50% at the age of 8–9 months and as low as 23% at the age of 15 months (Table 1). The NZB strain was the only other strain of mice reported to have an age-dependent decrease in the percentage of θ-bearing cells in the thymus[6]. A progressive age-related increase in the percentage of thymocytes carrying high levels of the H-2 alloantigen was observed (Table 1). In young SJL/J mice about 12% of the thymocytes carried high levels of H-2 antigen whereas at the age of 11 months the incidence increased to 58%.

Increasing incidence of immunoglobulin-bearing cells could be detected in SJL/J thymuses from the age of 5 months (Table 1), reaching a 50% incidence of IgG and 22% IgM-bearing cells in the thymus of 15-month-old SJL/J mice. The figures for IgG were higher than those of IgM. The possibility that thymocytes might carry both θ antigen and immunoglobulin determinants on their surface membrane was excluded by double labelling evaluation (see Table 1).

To check whether the surface immunoglobulins, as demonstrated by immunofluorescence, were synthesised by the cells themselves, thymus cells from 15-month-old SJL/J mice were treated with proteolytic enzymes and then kept in culture for several hours (as a positive control spleen cells were treated similarly). Surface immunoglobulins were evaluated using the direct immunofluorescence method[7]. Samples for immunoglobulin determinations were tested before and immediately after enzyme treatment and at 2 and 4 h after incubation. The capacity of the enzyme-treated cells to resynthesise immunoglobulins is shown in Fig. 1. The results indicated that the B cells were sensitive to trypsin or papain since a drop in surface immunoglobulins was observed following enzymatic treatment and recovery to normal levels was indicated 4 h after appropriate cultivation. Further analysis of these B cells present in the thymus of SJL/J mice was carried out by testing their functional ability to form anti-SRBC antibodies. Mice (10–12-month-old)

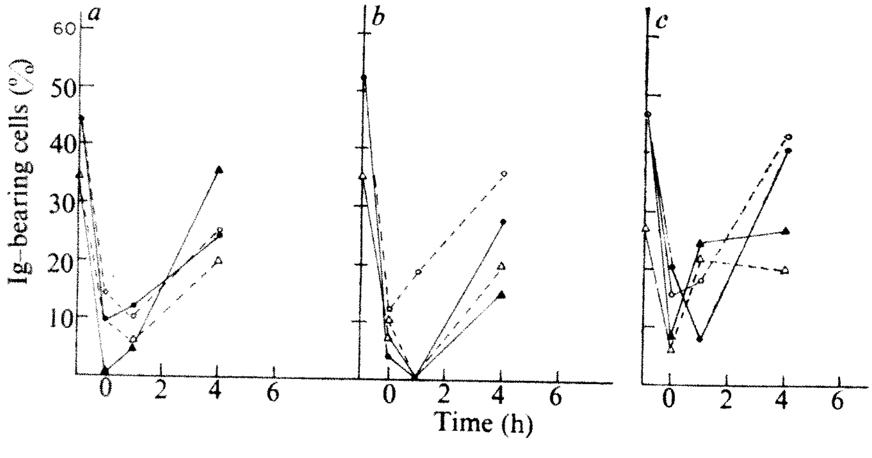

Fig. 1 Immunoglobulin production by SJL/J thymus cells after treatment with proteolytic enzymes. Thymus cells from 15-month-old SJL/J mice (*a* and *b*) or spleen cells from 2-month-old (*c*) animals were treated for 30 min (37 °C) with either (continuous line) trypsin (0.25% in Puck's solution) or (dotted line) papain (0.05% activated by 0.02 M dithiothreitol in the presence of 0.002% DNase); after enzyme removal the cells were washed three times and thereafter incubated in Eagle's MEM + 20% foetal calf serum at 37 °C in the presence of 10% CO_2 for several hours. *c*, Surface immunoglobulins were evaluated by the direct immunofluorescence method. △ and ▲, IgM; ○ and ●, IgG.

Table 1 Changes in cellular composition of SJL/J thymuses with increasing age

Age	Average thymus weight (mg)	% θ-Bearing cells Mean	% θ-Bearing cells Range	% High H-2^s-bearing cells Mean	% High H-2^s-bearing cells Range	% IgG-bearing cells Mean	% IgG-bearing cells Range	% IgM-bearing cells Mean	% IgM-bearing cells Range

15 months	140	23	8–40	—	—	50.2	30–63	21.8	10–35

Percentages of θ-bearing cells and high H-2^s-bearing cells were determined by cytotoxic testing (trypan-blue dye-exclusion). Anti-θ C3H serum (prepared by six weekly injections of 10^7 C3H thymus cells into AKR/J mice) or H-2 alloantiserum, shown to be cytotoxic only to thymocytes having high levels of H-2 antigen (obtained following six weekly injections of 10^8 SJL/J spleen cells into C3H mice), were used. Diluted antiserum (1:2–1:8) was added to 10^6 thymus cells; the mixtures were incubated for 20 min at 37 °C and after several washings with tyrode-BSA (0.1%) complement was added and the cells were further incubated for 30 min at 37 °C. The percentage of IgG and IgM-bearing cells was determined by direct immunofluorescence[7] with fluorescein-conjugated goat anti-mouse IgG or IgM sera (Meloy). Double labelling evaluation was carried out as follows. Thymus cells from 12-month-old SJL/J mice were incubated with fluorescein labelled anti-mouse Ig serum, the excess of serum removed from the cells by repeated washings and the cells treated with AKR anti-θ C3H serum followed by incubation with rhodamin-labelled anti-mouse IgG (Miles-Yeda, Israel). The cells were then tested under the fluorescence microscope. The immunoglobulin-bearing cells had a green yellow fluorescence (mostly caps), whereas the θ-carrying cells had a red fluorescence (mostly rings). No double-labelled cells were observed and the percentage of immunoglobulin and θ-bearing cells corresponded with the values obtained when each marker was tested separately.

received a single intraperitoneal injection of SRBC (0.5 ml 10% suspension) and 5 d later the plaque-forming capacity of thymus cells estimated[8] (mean values 1,415 ± 289 plaques per thymus). Antibody production by thymus cells was reported to occur only following thymus injury caused by antigen injection into the thymus[9].

Thymocytes bearing low levels of θ antigen and high levels of H-2 are considered to be the immunocompetent cells able to cause a GVH response. We therefore tested whether the age-related increase within the thymus of the H-2 population could be correlated with an increased capacity of T cells derived from older mice to induce a GVH response. Thymus cells(10^7) from 2,9 and 15-month-old SJL/J mice were injected into 10-d-old (SJL/J × C57BL/6) F_1 hybrid mice (8–10 mice per group) and estimating their spleen index 10 d later. A statistically significant increase in the ability of thymocytes from 9-month-old compared with 2-month-old mice to evoke a GVH response was indicated (spleen indices being 2.76 ± 0.10 compared with 1.71 ± 0.14, $P \ll 0.01$; thymus cells from 15-month-old mice yielded spleen indices of 2.35 ± 0.28; $P < 0.1$ for thymus cells from 2-month-old compared with 15-month-old mice). The results suggest that the θ-positive, high H-2 immunocompetent population is relatively and transitionally enriched in the thymus of 9-month-old animals, whereas in the 15-month-old thymus this population is reduced.

A certain thymus subpopulation within the 5–12 month age range could not be classified as T or B cells. The possibility that these cells may still be in an undifferentiated state and could thus differentiate into haematopoietic colony-formers when inoculated into lethally irradiated syngeneic mice was tested. Increasing numbers of thymocytes, taken from 2, 9 and 12-month-old SJL/J mice, were injected intravenously into irradiated mice and the occurrence of spleen colonies evaluated. An age-related increased ability of thymus cells to form colonies was noted (Fig. 2). Thymocytes from other strains of mice when injected in similar conditions cause the development of very few colonies[10].

Following the normal pattern of thymus growth and age-dependent atrophy[11] a secondary increase in thymus weight was observed in SJL/J mice from 7–9 months onwards (Table 1). This weight increase seemed to coincide with thymus repopulation by B cells. The thymus cells at this stage were hydrocortisone-resistant. The cellular composition and weight of 12-month-old thymuses were not altered following hydrocortisone treatment, whereas in the 2-month-old mice the hydrocortisone caused thymocyte destruction expressed in the marked drop of thymus weight and decreased incidence θ-bearing cells (Table 2).

Thus, with age increase the thymus of SJL/J mice includes

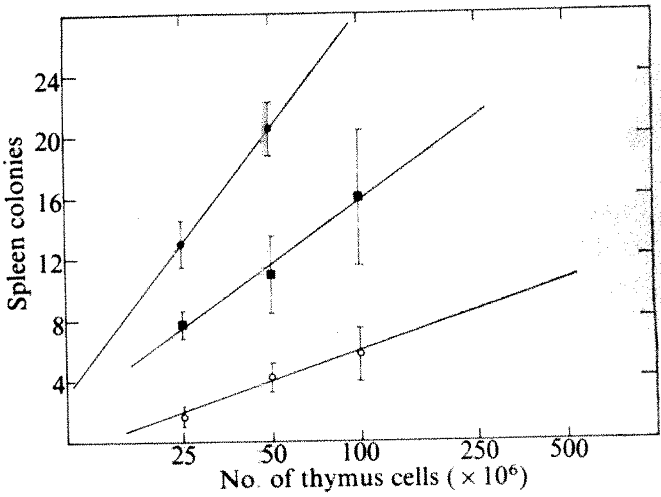

Fig. 2 Spleen colony-forming capacities of thymus cells from SJL/J mice of different ages. Increasing numbers of thymocytes (25 × 10^6–100 × 10^6) from 2(○), 9(■) and 12-month-old SJL/J mice (●) were injected intravenously into irradiated (750 rad whole-body exposure) SJL/J mice. Spleen colonies were counted 8 d later, after fixing the spleens in Bouin's solution (mean ± s.e.).

Table 2 Hydrocortisone effect on thymus weight and cellular composition of young and old SJL/J mice

Age (months) and treatment		Thymus weight (mg)	% θ-bearing cells	% high H-2-bearing cells	% Ig-bearing cells
2	Normal	57.3 ± 2.25	90.5 ± 0.37	16.5 ± 3.28	NT
	Hydrocortisone	11.7 ± 0.82	23.8 ± 4.07	91.8 ± 1.55	NT
12	Normal	59.5 ± 17.55	32.0 ± 6.58	62.0 ± 7.8	25.8 ± 7.49
	Hydrocortisone	49.3 ± 5.00	26.5 ± 3.49	89.3 ± 3.14	35.8 ± 4.02

SJL/J mice, 2 months old and 12 months old, were treated intraperitoneally with 2.5 mg hydrocortisone 48 h before they were killed, and their thymuses evaluated. Percentage of θ-bearing cells and high H-2-bearing cells was determined by cytotoxic testing, and the Ig-bearing cells were determined by direct immunofluorescence[7].

NT, not tested.

immunocompetent T and B cells (the influx of B cells being responsible for the secondary increase in thymus weight), and therefore possesses the cellular constitution and functional abilities of a peripheral lymphoid organ. The depletion of θ-bearing cells (from the age of 8 months onwards) and the occurrence of IgG and IgM-bearing cells in the thymus may be related to unique observations specific for the SJL/J strain of mice. Since immune functions involve the participation of thymus-derived lymphocytes, the comparative early decrease in the immune reactivity of SJL/J mice may be related to a 'defect' in a thymus 'regulating factor'. The susceptibility of SJL/J mice to develop B lymphatic leukaemia, following chemical carcinogen treatment[12], could perhaps be correlated with the unique capacity of B cells to home in the thymus. Debatable information has been provided concerning the presence of some B cells in the thymus of NZB mice[6,13]. Recently[14], it was reported that in the thymus of NZB/NZW mice immunoglobulin positive cells were observed at the age of 54–65 weeks.

Fusion of hen erythrocytes with yeast protoplasts induced by polyethylene glycol

POLYETHYLENE glycol (PEG) has been used to induce the fusion of protoplasts of higher plants[1,2]. Ahkong *et al.*[3] have also observed that PEG will cause hen erythrocytes to fuse to form binucleate and multinucleate cells. The availability of a common chemical agent that can be used effectively for the fusion of both animal cells and plant protoplasts has prompted us to investigate the possibility that PEG may likewise induce interspecific fusion between hen erythrocytes and yeast protoplasts.

Hen erythrocytes (Fig. 1*a*) and yeast protoplasts (Fig. 1*b*) were mixed in the cell ratios 1:250, 1:50, 1:10, 1:1 and 10:1, erythrocytes:protoplasts (approximately 6×10^8 cells in total). An appropriate volume of the protoplast preparation was centrifuged (1,000*g* for 3 min) and the supernatant removed. The appropriate volume of erythrocyte preparation was then added gently to the protoplast pellet and, after a brief centrifugation (800*g* for 5 min), the supernatant was carefully removed. The erythrocytes and protoplasts were resuspended and thoroughly mixed in 1 ml 40% w/v PEG solution (molecular weight 6,000; Koch-Light) in the HEPES-buffered Eagle's medium, *p*H 7.4, at 37° C, and then incubated at this temperature for 15 min, during which time the erythrocytes and protoplasts were observed to form nonspecific aggregates. The incubated suspension (1 ml) was diluted with 5 ml of the buffered Eagle's salt solution at 37 °C and, after centrifugation (800*g* for 5 min), the cells were resuspended in 1 ml of the same solution at 37 °C. At this stage, aggregation was less and the cells were more loosely associated. On continued incubation, the erythrocytes became swollen and cell fusion was observed by light microscopy. Samples were removed for electron microscopy at intervals of up to 1.5 h. These were fixed in 3% v/v glutaraldehyde (1 h at 22 °C) in buffered Eagle's salt solution and then treated as described previously[7].

Small variations from the above procedure, such as the use of yeast cells in stationary phase, markedly diminished the yield of fused cells. With the method described, approximately 0.1% of the erythrocytes were involved in interspecific fusion when the erythrocytes and yeast protoplasts were mixed in the proportions of 1:1 or 1:10 (Fig. 2*a*). With a cell ratio of 10:1 (erythrocytes:protoplasts), interspecific fusion was reduced and multinucleated erythrocytes were formed in relatively high numbers (Fig. 1*c*). With ratios of 1:50 or 1:250, very large protoplasts were seen, presumably the product of PEG-induced fusion of yeast protoplasts (Fig. 1*d*). Some of these giant protoplasts contained a few large, intracellular vacuoles, indicating that fusion of vacuoles had also occurred.

Further evidence for the occurrence of interspecific fusion was provided by electron microscopy (Fig. 2*b*). The erythrocyte plasma membrane seems to fuse with the yeast protoplast

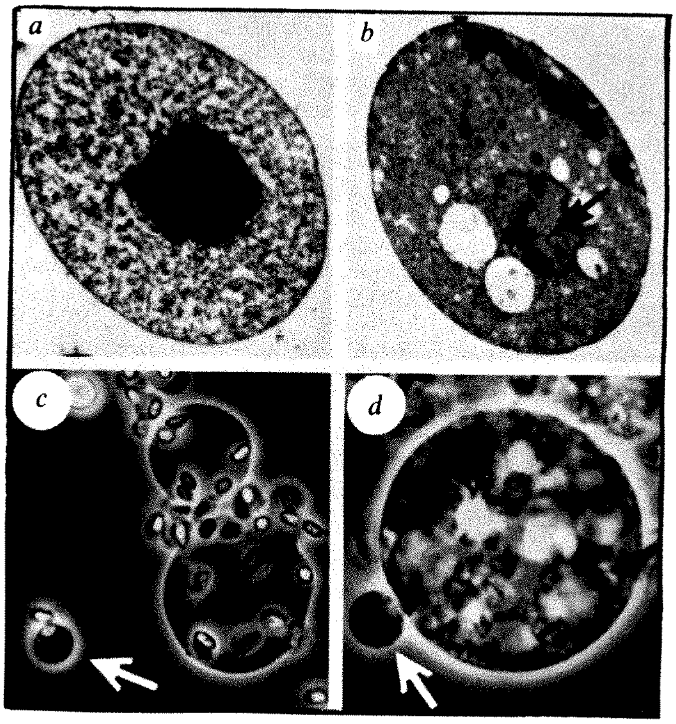

Fig. 1 Electron micrographs of (*a*) nucleated hen erythrocyte and (*b*) freshly isolated yeast protoplast showing nucleus (arrow), (×7,980). Hen erythrocytes were prepared as described previously, and suspended in a modified Eagle's basal salt solution[4], buffered at *p*H 7.4 with 20 mM HEPES buffer (approximately 6×10^8 cells ml^{-1}). Yeast cells, *Saccharomyces cerevisiae* strain NCYC 0263B, were cultured[5], and yeast protoplasts were obtained from cells in exponential growth using helicase[6]. The protoplasts were centrifuged (1,000*g* for 15 min) in a discontinuous density gradient of Ficoll 400 (Pharmacia, Uppsala, Sweden) dissolved in an osmotic stabiliser (0.7 M sorbitol, 0.01 M citric acid, *p*H 6.5); the osmotic stabiliser (5 volumes) was layered on 5% w/v Ficoll (8 volumes), which in turn was above a layer of 8% w/v Ficoll (8 volumes). The sedimented protoplasts were resuspended in the osmotic stabiliser (approximately 6×10^8 protoplasts ml^{-1}) and used immediately. *c*, Multinucleate erythrocytes formed by PEG treatment of erythrocytes and yeast protoplasts mixed in a cell ratio of 10:1. A single unfused erythrocyte (arrow) is shown for comparison (light micrograph, ×475). *d*, Giant yeast protoplast formed by PEG treatment of a mixture of erythrocytes and yeast protoplasts containing a large excess of protoplasts (cell ratio of 1:250) observed after incubation for 1 h in Eagle's medium at 37 °C. A single unfused yeast protoplast (arrow) is shown for comparison (light micrograph, ×950).

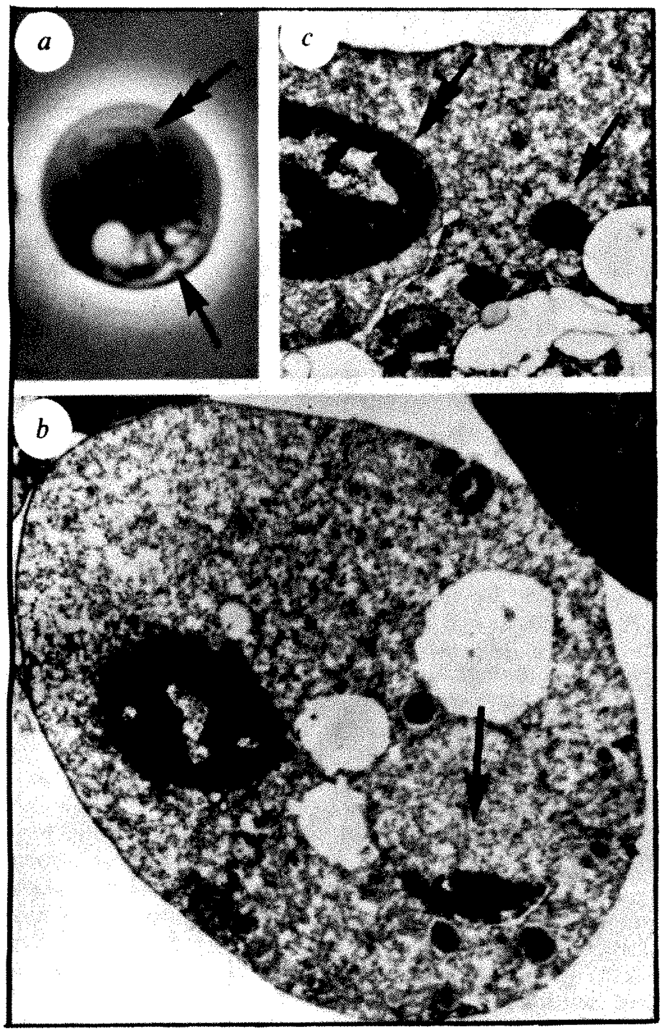

Fig. 2 *a*, Erythrocyte–yeast protoplast heterokaryon (yeast protoplast component—single arrow; erythrocyte component—double arrow) formed after PEG treatment of erythrocytes and yeast protoplasts mixed in the proportions of 1:10 observed after incubation for 40 min in Eagle's medium at 37 °C (light micrograph, ×618). Electron micrographs of (*b*) erythrocyte–yeast protoplast heterokaryon showing both the erthrocyte nucleus and the yeast nucleus (arrow), (×12,540) and (*c*) formation of a broad cytoplasmic bridge between an erythrocyte (double arrow) fusing with a yeast protoplast (single arrow), (×14,060).

plasma membrane, and as a result, broad cytoplasmic bridges are formed between adjacent cells (Fig. 2*c*).

The fact that the plasma membranes of cells from genera as widely separated as hen and yeast can fuse in appropriate experimental conditions is of particular interest, and studies are in progress to see if it will be possible to culture the heterokaryons obtained. These investigations may well further our knowledge of membrane structure, and of nuclear and cytoplasmic interactions in such animal–fungal heterokaryons. In addition there are many fundamental morphological and biochemical problems that could be investigated with the aid of interspecific fusion of this kind.

Visual control of head movements during avian locomotion

THE impression that pigeons, chickens, and many other common birds bob their heads backward and forward as they walk is compelling but illusory. In reality, the walking bird thrusts its head forward, then holds it nearly stationary while the neck retracts and the body catches up. The head moves backward and forward with respect to the body, but moves only forward in the environment. Although this was demonstrated on film more than 40 years ago[1], theorists concerned with the evolution of visual systems[2–4] continue to suggest that a back and forth oscillation of the head is important in avian vision.

The rhythm of head movement may, by a reflex action, aid balance or it may become entrained by other endogenous rhythms during walking[5]. Since vestibular stimulation can induce rhythmical head rotations[6] and since doves' linear head movements have the same rhythm as head rotations[7], stimulation of the labyrinths during locomotion may elicit the periodic head movements. Finally, since rotations of the visual field induce periodic optokinesis in many species[8] visual displacement may also be responsible for rhythmical linear head movements. A series of experiments were carried out on the Ring Dove (*Streptopelia risoria*) to dissociate the three factors most likely to control head movements during locomotion: movement in the visual environment; acceleration in the inertial (labyrinthian) environment; and the mechanics of stepping.

A dove was filmed from above as it walked about and fed in a cylindrical cage (Fig. 1*a*) and successive single frames of the recording were analysed. The normal pattern of horizontal head movement was determined relative to the cage, to the camera support, and to the bird's body. As a control for the effects of the apparatus used in later experiments, a small plastic platform was temporarily glued to the feathers on the bird's back and a rod (held vertical by a counterbalanced thread) was loosely attached to a pivot on the platform (Fig. 1*b*). When the dove was recorded in the cage, the effects of the platform and vertical rod on feeding behaviour were negligible and the patterns of head movement were normal.

A duplicate cage was constructed from extremely lightweight material. The entire cage weighed 180 g, approximately the same as the weight of a dove. The cage was supported over a level plate by hundreds of miniature ball bearings. The platform on the bird's back was attached by a counterbalanced joint to a rigid column fixed below the camera (Fig. 1*c*). Without supporting the bird, the joint permitted the vertical displacements and pitch and roll movements normal in walking, but restrained the bird's body from any horizontal linear displacements or

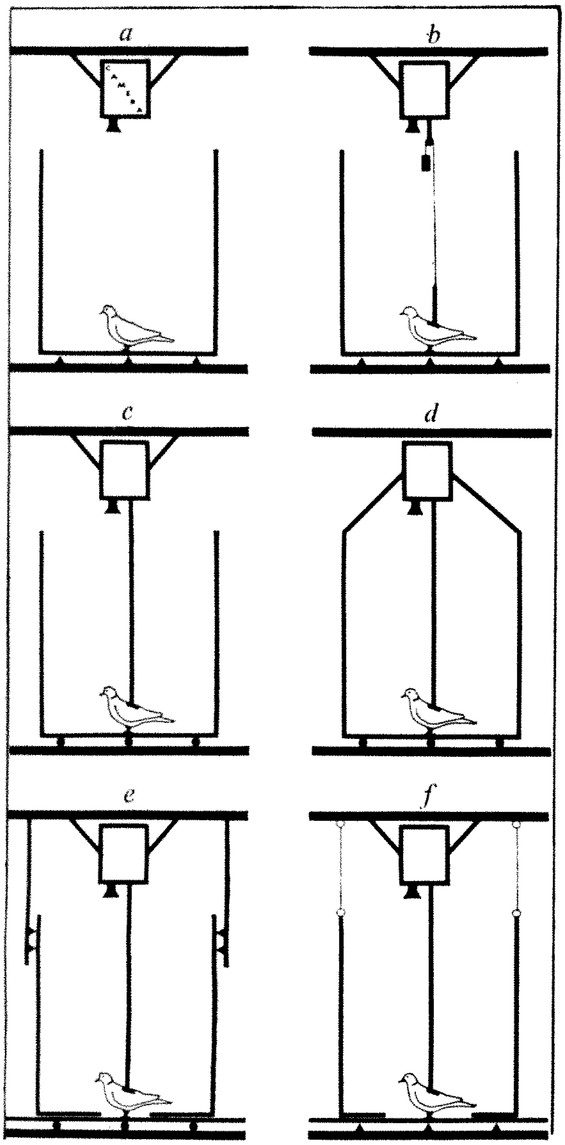

Fig. 1 *a–f* The six experimental conditions discussed in the text. A television or cine camera was mounted on a frame vertically above a cylindrical cage 50 cm in diameter with a 60 cm high wall. ▲, Fixed cage support; ●, ball bearing cage support. The sliding cage was constructed from expanded polystyrene (2 mm thick) with the underside of the floor and lower wall reinforced by 0.5 mm cellulose acetate. The ball bearings were 300–400 µm polystyrene beads. Three birds participated in all six phases of the experiment and three others participated in only the first three phases. Each day each bird was tested in only one cage configuration. The floor and walls of the cage were distinctly patterned and a variety of seeds were scattered on the cage floor. In the first four phases, the bird was allowed 1 h to adapt to the cage before fresh seeds were added and the recording started. In the last two situations recording was started soon after the bird was placed in the cage.

rotary movements. Thus, when the bird took a step, rather than moving across the floor, the floor moved under the bird. Similarly, rather than turning in the cage, the cage rotated around the bird. The movements of the floor and walls relative to the bird were the same as would have occurred in free movement.

When recordings of the bird walking and feeding in this cage were analysed, head movements were normal with respect to the visual world (the cage) and the bird's body, but abnormal with respect to the inertial world (the camera supports). Whereas the head continued to be alternately thrust forward and held still in visual space, in inertial space it moved backward after each forward thrust. This backward movement in the inertial frame of reference would not normally take place during locomotion.

The camera was then detached from its fixed supports and attached to the moveable cage (Fig. 1*d*). The cage was pushed forward or rotated by hand at speeds approximating the bird's normal rate of travel. This would show if progression through inertial space could be sufficient to sustain periodic head movements. The dove's head stayed locked to its visual world and did not oscillate with respect to the body or surge in inertial space.

To determine the role of stepping movements, the camera was remounted on its fixed support and the cage rigidly attached to the same framework. A large false floor, adjusted to equal the dove's own weight, was mounted on bearings immediately below the real cage floor which had a hole cut in it. The bird was placed in the cage on the false floor and attached to the joint assembly (Fig. 1*e*). Recording was started and continued until spontaneous walking began. If this did not occur within 15 min, walking was induced by gently pulling on the false floor. The experiment was repeated three times with each dove and in each case the bird either extended its neck gradually forward and started running until it thrust the false floor out from underneath it or squatted and started peering rapidly around. There was no evidence of the 'bobbing' of the head observed during normal locomotion, although the doves were obviously reacting to the absence of visual feedback from their stepping.

In a complementary test, the hole in the cage floor was enlarged and the cage was suspended by thread from the ceiling. The false floor was fixed (Fig. 1*f*). After the bird was attached to the camera column, the cage was moved by hand at approximately the same speed used in condition (*d*). When the cage was rotated, the bird showed the classical optomotor response[6,8] of the head: alternately stabilising in visual space and saccadically moving to a new position. When the cage was moved smoothly in a rostral to caudal direction (up to 20 cm displacement), the bird's head was alternately stabilised and thrust forward in its visual space while it oscillated back and forth with reference to the body and inertial space.

Conditions *a* and *b* established the range of normal patterns of head movement shown by doves in the cylindrical cage and showed that having a vertical rod attached to the bird's back did not alter the normal pattern of head movement. Condition *c*, in which the cage moved about the bird rather than the bird about the cage, demonstrated that progression through inertial space is not necessary for the normal pattern of head movement. When the whole cage was moved with the bird fixed in the cage (condition *d*), it showed that progression through inertial space is not sufficient, in itself, to induce a normal periodic pattern of head movement. Condition *e* demonstrated that the mechanics of stepping are not sufficient to generate the periodic head movements normally seen. Condition *f* showed that the mechanics of stepping are not necessary for the normal pattern of head movement but that displacement through visual space is a sufficient condition. These results hold both for linear and angular movements.

These experiments demonstrate the primacy of vision in regulating periodic eye and head movements in the dove. The rhythmical alternation of visual stabilisation and rapid reorientation described here is not limited to walking birds with dove-like head movements[9]. Many long-necked birds rhythmically dart their heads about while inspecting possible food sources. Some of those with shorter necks and large beaks show saccadic exploratory eye movements. Hopping birds with short necks have, by necessity, a saltatory mode of head and eye movement. That birds of diverse shape and mode of locomotion show similar patterns of head and eye movement should be important to theories of the evolution of visual perception[10] and suggests that the neural substrate of this mode of visual exploration is very conservative during avian evolution.

This work was carried out while the author was a postdoctoral fellow in the Department of Psychology of the University of Edinburgh working with Dr C. Trevarthen and Professor D. M. Vowles, and was supported by a US NIMH fellowship and by an SRC research grant to Professor Vowles.

Visual detection analysed in terms of luminance and chromatic signals

THE ability to discriminate surfaces of different colour and luminance is a basic property of human vision. This has been studied by determining visual thresholds for test stimuli of one colour superimposed on a background of another colour. Stiles has suggested that the observer samples the responses to the test flash from a number of 'mechanisms' each of which adapts independently to the background[1,2]. In the simplest form of the model, the responses of the different mechanisms to the test flash are also treated independently, that is, a flash is seen if it exceeds the threshold criterion of any of the mechanisms. The spectral sensitivities of Stiles' mechanisms (to both test and background stimuli) are similar to the absorption and action spectra of the three normal types of human cone[3-5]. Thus, as a simple approximation, visual mechanisms correspond to individual classes of cone and they adapt and are sampled independently; this scheme would be consistent with the demonstration of adaptation occurring within monkey cones[6].

This simple model has proved to be of great value under a wide range of adaptation conditions[1,2], but certain objections have been raised. Electrophysiological studies have shown that the output from the cones is recoded in terms of luminance and colour information at an early stage[7-9]; it is therefore not easy to see how the outputs from different cone types can be sampled independently. Psychophysically, Stiles has shown that up to seven mechanisms must be proposed to explain his data[2], although there are thought to be only three types of cone. The spectral sensitivity of at least one of Stiles' mechanisms (π_5) cannot correspond to a cone action spectrum, as can be shown from colour matching data[2]. The model cannot explain the inhibitory interactions which may be demonstrated when different colours of test flash are superimposed[10,11]. It is also inconsistent with the 'supersummation' effects observed when different colours of background light are added together[12]. Finally, the model predicts that the spectral sensitivity for a test flash on a white background should correspond to an upper envelope of the sensitivities of the three cone types and so should have a rather broad maximum in the region 540–570 nm; however, the observed sensitivity curve (Fig. 1, ○) shows relatively sharp peaks at about 610 and 530 nm which cannot be fitted by Stiles' mechanisms or by the cone action spectra[13].

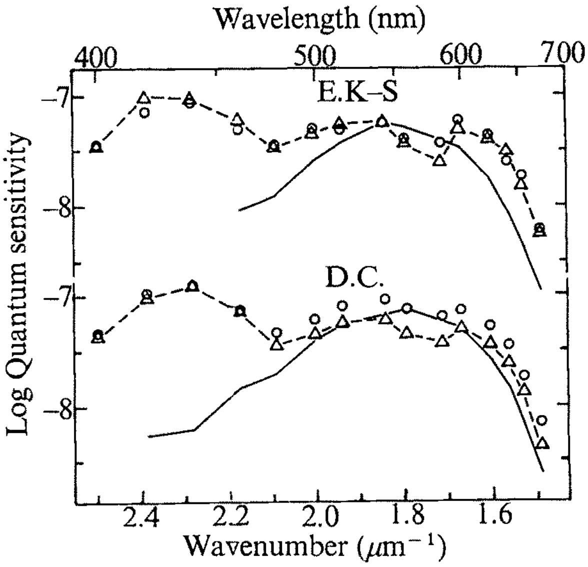
To overcome some of these problems, Sperling and Harwerth[13] have proposed that there is a general linear subtractive interaction between the outputs of the 'red' and 'green' sensitive cones, that is, the red cone response to a test flash is reduced in proportion to the green cone response and vice versa; in this way, they could fit the spectral sensitivity data for a white background. This subtractive process could presumably form the basis for the inhibitory interactions between test stimuli mentioned above[10,11]. It may also correspond to the red–green opponent colour responses proposed by Hering (1875) and by Jameson and Hurvich[14] and which have been demonstrated in single units of the monkey visual system[7-9].

According to Hering's classical theory, the opponent colour channel is concerned with the signalling of chromatic as opposed to luminance information. Thus, if the opponent colour system is indeed responsible for visual detection of spectral flashes on a white background, the colour of the test light may be expected to be observable at the detection threshold. This prediction has been tested with a two-channel Maxwellian view apparatus[15] using a 1° 200 ms test flash on a white background (Fig. 1).

Although detection sensitivity tends to be slightly higher than colour sensitivity throughout the red–green range of the spectrum, there is reasonable agreement between the two sensitivities, supporting the idea that opponent colour mechanisms are mainly responsible for detection in this situation. This conclusion is further supported by the observation that red and white test stimuli at their respective detection thresholds are as easily discriminated from each other as each is discriminated from a blank stimulus (P. E. K-S., unpublished); the colour of the red stimulus is thus detectable at threshold. This observation is consistent with other psychophysical studies[16,17].

A surprising aspect of this interpretation is that no contribution from the luminance signalling system[7-9,14] has been assumed; one may expect this to have contributed a relatively broad peak near 550 nm. I believe that the lack of evidence of

Fig. 1 Spectral sensitivity curves determined from thresholds for a circular 1° 200 ms foveal test flash presented on a 4° white background of 1,000 trolands (luminance in candelas m^{-2} × area of pupil in mm^{-2}) and about 3200 K colour temperature. For the two subjects, E. K-S. (age 34) and D.C. (age 31): ○, detection thresholds; △ and dashed lines, thresholds for determining the colour of the test stimulus; continuous curves, sensitivity of the luminance channel to the test stimulus (the shapes of these curves were derived from the thresholds for detecting 25 Hz flicker on the same white background, whereas the vertical positions were derived from the corresponding curves in Fig. 2). Test wavelengths were presented in random order; thresholds were determined by subject setting, and the plotted points correspond to means of three or more determinations (s. e. typically 0.04 log units). Sensitivity is expressed as reciprocal quanta s^{-1} degree^{-2}.

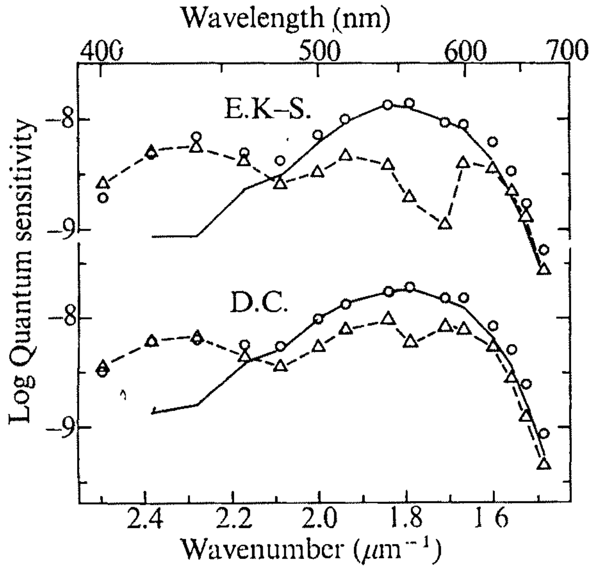


contribution from the luminance system is caused by the low sensitivity of this system in the conditions of Fig. 1, perhaps for three reasons. First, the relatively long duration (200 ms) of the test flash in Fig. 1 favours the opponent colour system relative to the luminance system because of the greater temporal integration in opponent colour channels[18,19]. Second, it can similarly be argued that the relatively large (1°) test flash may again favour the opponent colour system which has a greater spatial integration than the luminance system[20,21]. Third, it is possible that the white background, which is a strong stimulus for the luminance but not for the opponent colour system, may cause a corresponding reduction in sensitivity, specifically within the luminance channel.

It is possible to test these ideas by altering the experimental conditions in the ways expected to favour the luminance channel. For example, the luminance of the white background may be reduced in steps and finally to zero (absolute foveal threshold); when this is done, there is a tendency for the two peaks in the red–green range to become less prominent and, as predicted, a broad peak near 550 nm becomes apparent[13,22]. Use of a very small test spot (0.05°) on the white background of Fig. 1 also yields a smoother sensitivity curve with a broad peak near 560 nm (P. E. K-S., unpublished).

The third alternative procedure used for favouring the luminance channel, that is by reducing the test exposure to 10 ms, is illustrated in Fig. 2. A relatively broad maximum of detection sensitivity at 550–560 nm is found for both subjects. Similar measurements have been reported by Ikeda and Boynton[23]. The interpretation of this maximum as the contribution of the luminance channel is supported by two observations. First, the colour sensitivity (Fig. 2) is considerably lower than the detection sensitivity in this region of the spectrum (particularly for subject E. K-S.). Secondly, the sensitivity of the luminance system may be estimated by determining the subject's thresholds for detecting high frequency (25 Hz) flicker on the same white background; the opponent colour channels should contribute little to these data since they are known to have a poor response to high frequency flicker[18]. The continuous curves in Fig. 2 are derived in this way and fit well the central region of the detection sensitivity curves (about 500–600 nm for E. K-S. and about 480–580 nm for D.C.).

Fig. 2 Spectral sensitivity curves for detection (○) and for colour (△ and dashed line) as in Fig. 1 but for a 10 ms instead of a 200 ms test flash; continuous curves, sensitivity of the luminance channel determined from 25 Hz flicker thresholds (these curves have been shifted vertically to match the detection sensitivity curve near 550 nm). To a good approximation, detection sensitivity corresponds to colour sensitivity or luminance sensitivity, whichever is the greater.



It is now possible to understand why there is no evident contribution from the luminance channel for the 200-ms test flash (Fig. 1). For the white background (Figs. 1 and 2), the subjects were about 0.6 log units more sensitive to a 200-ms than to a 10-ms white test flash. Thus, we may expect the luminance channel to be 0.6 log units more sensitive for the 200-ms test flash of Fig. 1 than for the 10-ms test flash of Fig. 2, and the continuous curves of Fig. 1 are the corresponding sensitivities of the luminance channels derived in this way. The luminance sensitivity (Fig. 1) is less than the colour sensitivity except for a restricted region around 570 nm and this explains why the effect of the luminance system is not evident for the detection of a 200-ms test flash.

In summary, it is proposed that a test flash is detected either by its luminance or by its colour; this conclusion is consistent with recent psychophysical experiments[11,24,25]. Thus, the spectral sensitivity for the detection of a test flash (Figs. 1 and 2) corresponds approximately with the upper envelope of the colour sensitivity and the luminance sensitivity. The results indicate that there may be some probability summation between the two systems when they have nearly equal sensitivity (for example, for 10-ms red test flashes, Fig. 2). It is probable that the major part of light adaptation occurs within the cones[6], but it may also be necessary to consider adaptation within the luminance and opponent colour channels. Thus some adaptation in the photopic system may take place at a point where the signals from receptors have been 'pooled'; Rushton[26] has demonstrated the importance of an adaptation pool in the scotopic system. Finally, we do not have direct access to the outputs from different classes of cones; we can only sample this information indirectly after it has been reprocessed in terms of luminance and colour information.

A final comment is needed about the relation between the opponent colour and luminance systems. It is quite possible that, in some situations, opponent colour cells may be involved in the transmission of luminance information. For example, the outputs from red-on-centre and from green-on-centre geniculate cells[8] could be combined in the cortex to form a unit with luminance-type properties; the present experiments do not rule out this possibility.

This work was supported by a grant from the Royal Society and by a research grant from the SRC. I thank Mr D. Carden for assistance and for acting as subject, and W. S. Stiles, R. M. Boynton, P. Gouras, D. Regan, C. F. Stromeyer, J. R. Cronly-Dillon, J. J. Kulikowski and D. Carden for their comments on the manuscript.

Sensitivity of self-potentiating effect of luteinising hormone-releasing hormone to cycloheximide

THE hypophysiotropic luteinising hormone–releasing hormone (LHRH) has a number of distinct actions on the anterior pituitary gland. In addition to stimulating the release and increased synthesis of gonadotrophins[1], this peptide also has a priming or self-potentiating effect so that intermittent stimulation of the pituitary with identical doses of LHRH causes a progressively increasing series of responses of luteinising-hormone (LH) secretion. Self-potentiation by LHRH has been observed *in vivo* in rats[2] and man[3] and may play an important role in the generation of the LH surge which precedes ovulation. The effect can be obtained[4] following repeated, brief exposures of the isolated, perifused rat pituitary gland to LHRH and the time course of development and decay of the potentiated state in these conditions is similar to that observed in the intact rat[2]. We have investigated the effects of an inhibitor of protein synthesis on this phenomenon and report here that cycloheximide suppresses the priming effect of LHRH without impairing the acute response of LH release.

Pituitary glands from four dioestrous female rats were halved and divided into two groups of paired halves. Each group was placed in an identical Millipore Swinnex filter chamber and perifused simultaneously at 37 °C with Krebs–Ringer bicarbonate medium (*p*H 7.4) containing bovine serum albumin (2.5 g l^{-1}), glucose (2 g l^{-1}) and gassed with 95% O_2–5% CO_2 (v/v). The flow rate was maintained at 0.2 ml min^{-1} by means of a peristaltic pump and the effluent medium was collected every 10 min (2 ml fractions) and assayed for LH using an NIH radioimmunoassay kit.

Cycloheximide (5 μM) was added to the medium used to perifuse one group of halved pituitaries whereas the other group received only the control medium. After an initial period of 100 min in which the secretion of LH was allowed to decline towards basal levels, both groups of halved glands were subjected to 5 mins perifusion with 10 ng of synthetic LHRH dissolved in 1 ml of perifusion medium, introduced by transferring the inlet tube of the system to the test sample. Identical challenges with LHRH were administered at intervals of 1 h for a further period of 4 h and the effects on LH secretion in both groups are shown in Fig. 1.

Control and cycloheximide treated groups both showed similar patterns of LH secretion during the preliminary period of perifusion and also in response to the first stimulation with LHRH, which was given before LH secretion had reached basal levels. With subsequent exposures to LHRH, however, only the hemipituitaries perifused with control medium showed the typical pattern of increasing responsiveness to LHRH and after five such challenges the rate of secretion of LH had risen to about five times that of the glands treated with cycloheximide. The latter did not exhibit a potentiated response and a series of equal peaks of LH secretion were obtained in the presence of 5 μM cycloheximide.

Inhibition of the self-potentiating effect of LHRH has been consistently obtained in similar experiments in which concentrations of cycloheximide ranging from 5 μM to 250 μM were used. In no case was the acute release of LH in response to LHRH abolished. Dissociation between the acute release of LH and the development of enhanced responsiveness to a series of LH-releasing stimuli has also been obtained in preliminary experiments in which isolated perifused pituitary glands were exposed for 5 min to medium containing 50 mM K^+. Osmolarity was maintained by adjusting the Na^+ concentration and the stimulus was administered at 1-h intervals. The high potassium medium caused an acute release of LH similar to that observed with LHRH but, as in the presence of cycloheximide, the series of LH peaks were of equal magnitude and did not exhibit the increased responsiveness shown by glands primed with LHRH.

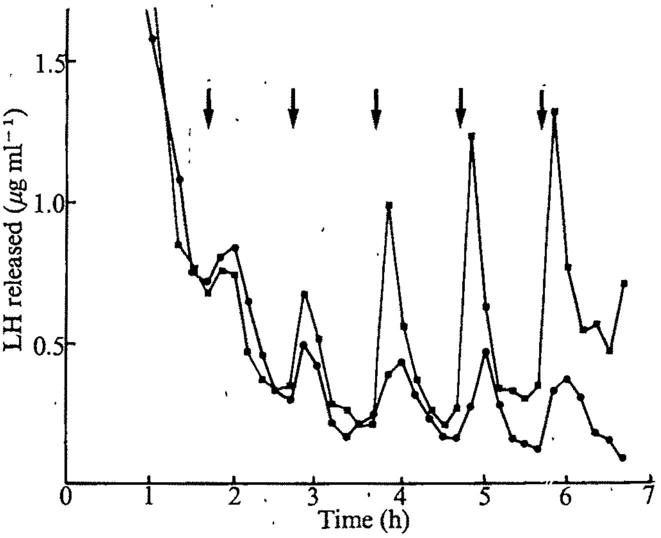

Fig. 1 Effect of cycloheximide on stimulation of LH release by LHRH. Two groups of paired, halved rat adenohypophyses were simultaneously perfused with Krebs–Ringer bicarbonate medium alone (■) and containing 5 μM cycloheximide (●). Glands were exposed to synthetic LHRH (10 ng ml^{-1}) for 5 min at the times indicated by arrows. LH released to the perifusion medium in 10 min intervals was measured by radioimmunoassay and results are expressed in terms of the NIAMD-rat LH-RP-1 reference preparation. Cycloheximide abolished the self-potentiation produced by LHRH without reducing the acute release of LH.

These results show clearly that the augmented release of LH which occurs from the primed pituitary gland represents a specific response to the hypophysiotropic hormone rather than a nonspecific sequel to the discharge of LH. Release of LH evoked by LHRH in the presence of cycloheximide or induced by depolarising levels of K^+ does not cause a potentiated response to further stimulation. The priming effect would seem to involve the synthesis of new proteins and it has been suggested that increased synthesis of LH may be important[3]. Only a small percentage of the LH content of the gland is, however, released in response to acute stimulation with a supramaximal dose of LHRH. An intermittent exposure to LHRH in the presence of cycloheximide does not cause a diminution of the acute secretory response. It is likely that the availability of LH is not a limiting factor and that the synthesis of some other component of the release mechanism may be essential for self-potentiation to occur. The effects of LHRH and cycloheximide on the incorporation of labelled amino acids into LH and various subcellular components are being studied and should resolve this issue.

This work was partly supported by an MRC programme grant. We thank C. O'Neil and Mrs J. Pennington for technical assistance. Rat LH immunoassay materials were provided by the NIAMD–NIH rat hormone distribution programme and the LHRH was donated by Roche Products Ltd.

Inhibition of airlicking in thirsty rats by cooling the preoptic area

THIRSTY rats lick avidly and persistently at a stream of air flowing through a drinking tube[1], behaviour which is not dependent on the previous experience of drinking water through a drinking tube[2] or on olfactory cues[3]. The most plausible explanation for the rewarding property of airlicking is that it is a result of evaporative cooling of the orolingual region. Heating and humidifying the air so as to decrease its cooling power reduces airlicking[4]. In addition, tongue cooling alone is rewarding for thirsty rodents[5], and cold water has a greater satiating effect on water intake than warm water[6]. These observations seem to indicate that because airlicking leads to tongue cooling, it thereby reduces thirst and the reduction of thirst reinforces airlicking. Airlicking cannot be mediated entirely by tongue temperature receptors, however, because lingual denervation by bilateral section of the lingual, chorda tympani and one branch of the glossopharyngeal nerves has no influence on airlicking[7]. It is not clear whether central stimuli that affect water drinking and satiation will similarly influence airlicking. Temperature-sensitive neurones are located in the preoptic area (POA) and hypothalamus[8], and since cooling of the POA reduces water intake in thirsty animals[9], we tried to determine if cooling of the POA reduced airlicking. We found that acquisition of airlicking behaviour was completely blocked by POA cooling in naive animals and reduced about 50% in experienced animals.

Unilateral water-perfused thermodes[10] with thermistors fixed to the tips were placed stereotaxically into the POA of six naive and two experienced airlickers and into the posterior hypothalamus (PH) as a control procedure in one naive and one experienced airlicker. The animals were adult, female Sprague–Dawley rats. Of seven control animals, four were unoperated and three received either a clogged thermode, a thermistor alone, or a cannula, all in the POA.

Histology showed the POA thermodes were located close to the midline between A7470 and A8620 according to the atlas of König and Klippel[11], while those in the PH were centred at A3180.

Water deprivation for 48 h preceded the first airlicking test, and thereafter a single water ration sufficient to maintain body weight at 85% of *ad libitum* weight was given in a Richter tube immediately after each test. Food was always available except during testing. Daily, 30-min tests were conducted in a model 1316 Lehigh–Valley test enclosure modified so that a metal drinking spout could be mounted with the aperture 5 mm outside a 1.4×3.2 cm slot on the right-hand side of the front panel. An airflow of 6 l min^{-1} through the 3 mm aperture of the tube was measured continuously with a Gilmont flowmeter. Relative humidity of the air was 27–30%. The number of licks and time in contact with the tube were measured by an electronic drinkometer circuit and recorded on electromechanical counters and a cumulative recorder.

The thermodes in the POA of the naive subjects were cooled to 33 °C during the first five tests for one subject, the first seven tests for two subjects, and the first fourteen tests for three subjects and the one animal with a posterior thermode. After termination of the cooling tests, daily tests were continued for at least 14 d. The experienced airlickers were given 28 daily tests to establish stable behaviour and after 7 d of recuperation from surgery, four tests were given to assure recovery of airlicking performance. The thermodes were then cooled to 33 °C for seven tests.

The data for the control animals were pooled since there was no difference between the operated and unoperated subjects. All control animals and the subject with a PH thermode cooled to 33 °C licked persistently at the airstream during the first and all subsequent tests. The mean number of licks during the first test was 3,266 for the control animals and 3,356 for the PH subject. The animals approached an asymptotic level of licking after a few days and averaged 6,192 licks per test (range 5,090–8,024). The animal with a PH thermode averaged 7,307 licks per test.

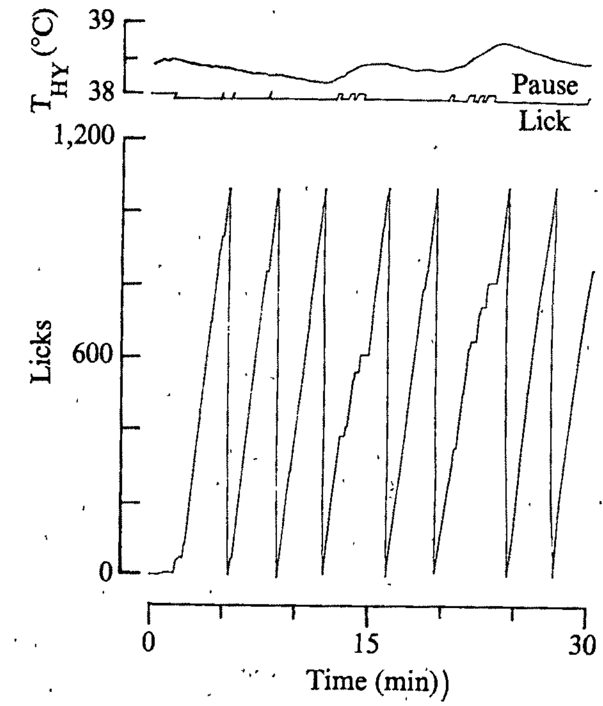

Fig. 1 Hypothalamic temperature (T_{HY}) and cumulative number of licks. The event channel (middle trace) indicates pauses in licking longer than 1.5 s.

Cooling of the POA to 33 °C precluded the acquisition of airlicking behaviour, regardless of whether cooling was applied for 5, 7 or 14 daily tests. The animals explored the cage and sampled the airstream during the first test, obtaining an average of 50 licks. During the remaining tests they rarely licked at the airstream, obtaining an average of only 11 licks per test. The airstream was not completely neutral, as the animals frequently sniffed at or to the side of the tube. This behaviour was interspersed with exploration of and sniffing at other parts of the cage as well as grooming.

The post-test rectal temperature of the control animals was 38.5 °C, whereas that of the POA subjects was consistently ($P<0.01$) elevated following tests with cooling (mean 39.6 °C, range of means 39.3–40.0 °C). Post-test rectal temperature of the subject with a posterior thermode, and of the subjects with POA thermodes when not cooled, never exceeded 39 °C. The elevation of post-test rectal temperature following cooling of the POA indicates the thermodes were in a thermally-sensitive region. It also raises the possibility that the suppression of airlicking may be a secondary effect of the elevated core temperature resulting from POA cooling. Measurement of the temperature of the PH during cooling of the POA, however, showed that a peak temperature of 40.2 °C occurred between 12 and 24 min after the start of the session. Thus, there was opportunity to airlick before the development of core hyperthermia. In addition, if it is the cooling effect of airlicking that is reinforcing[5], then the airstream should have been more reinforcing after the development of hyperthermia, which it did not seem to be. Figure 1 shows that airlicking is accompanied by a gradual fall in POA temperature. The observed rate of decrease is extremely small, of the order of 0.02–0.05 °C min^{-1} and there is an increase in temperature brought about by pauses in airlicking. During similar tests, rats airlicked for one or two hours without apparent satiation[1]. Perhaps the absence of satiation is related to the weak central cooling of airlicking in conjunction with rapid rewarming of the POA during pauses.

The animals that received cooling of the POA had difficulty acquiring airlicking behaviour after the end of the cooling tests. Two animals failed to airlick, two licked sporadically and two developed normal airlicking during the fifth test. There was no consistent relationship between the number of days of cooling and difficulty in acquiring airlicking behaviour. Perhaps the failure to develop normal airlicking immediately was a result of the subjects having learned during the cooling trials that the airstream was not rewarding.

Cooling the thermodes in the POA of two experienced airlickers for seven consecutive tests reduced airlicking an average of 40% for one subject and 53% for the second subject. Airlicking was reduced 6% for the PH subject. Thus, cooling of the POA reduced but did not eliminate airlicking once the behaviour had been acquired, whereas cooling of the PH had no substantial effect on airlicking by either the naive or the experienced subjects.

Different processes may be involved in the initiation and in the maintenance of airlicking since cooling of the POA completely blocks licking in naive but not in experienced animals. Perhaps direct conductive and convective cooling of the POA is important during acquisition of the behaviour while orolingual stimulation is sufficient to mediate airlicking once the behaviour has been acquired.

These results demonstrate that, like water drinking, airlicking by experienced rats is inhibited by cooling of the POA. Thus at least one specific central stimulus that affects water drinking affects airlicking in a similar way.

Evidence for nuclear control of amino acid transport in cultured cells

Cells incubated in an amino acid-free Krebs–Ringer buffer, or grown in medium with a reduced amino acid concentration, respond by increasing their ability to actively transport amino acids[1-3]. Studies using inhibitors of mRNA transcription and translocation suggested that this regulatory control involves mRNA transcription and the synthesis of protein intimately concerned with the transport process. We determined nuclear involvement using cells enucleated by prior treatment with the fungal metabolite cytochalasin B (ref. 4). The results presented here suggest that the nuclei of HeLa cells are important for maintaining and modifying their amino acid transport capacity in response to a reduction in the external amino acid concentration.

Growth in low amino acid BME resulted in an increase in V_{max} and a decrease in the apparent K_m value for influx. In a typical experiment, V_{max} increased from 53.51 to 70.01 pmol cm^{-2} s^{-1} and K_m decreased from 2.39 to 1.24 mM. Treatment with cytochalasin B alone did not affect glycine influx and did not prevent the transport modifications observed in normal cells. In normal cells grown in low amino acid BME (Fig. 1), glycine influx increased by 51%, whereas in enucleated cells it decreased by 48% (significant at $P<0.001$ and $P<0.02$ respectively), indicating the involvement of the nucleus in the membrane response. It seems likely that it occurs in two stages: an afferent pathway to the nucleus and an efferent pathway from the nucleus to the cell membrane. The nucleus itself, for example, could detect a lowered concentration of amino acid in its immediate environment and thus act as the initiator of the response. To test this possibility, the intracellular pool size was manipulated directly in cultured *Xenopus laevis* kidney cells, during low amino acid growth, by periodically loading the cells with high concentrations of amino acid. Figure 2 shows that the cells responded to alteration of external concentration of amino acid despite a high intracellular concentration, indicating that intracellular amino acid pool size was not a factor limiting control. As amino acids are probably evenly distributed between nucleus and cytoplasm[5], it was improbable that removal of the nucleus interfered with the initiation of the regulatory signal.

An alternative mechanism of substrate control of transport is by way of the rate of carrier activity per unit time. Enucleation itself caused a reduction in transport capacity; 0.5 h after enucleation, influx was decreased by 50% if expressed per cell.

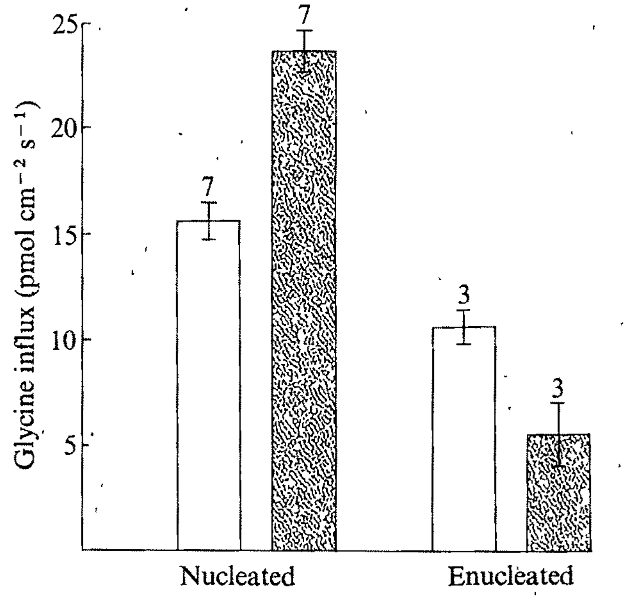

Fig. 1 The glycine-transport response of normal and enucleated HeLa cells to growth in low amino acid medium. HeLa cells were grown in normal Basal Medium Eagle (BME) on either glass coverslips (diameter 2.2 cm) or Falcon plastic Petri dishes (diameter 5 cm) to a final density of about 8 × 10^4 cells cm^{-2}. The cells were then incubated in growth medium containing 5 µg ml^{-1} cytochalasin B for 10 min and spun at 10,000 r.p.m. for 50 min at 37 °C. This procedure produced 60–80% enucleation and results were corrected for 100% enucleation. The cells were allowed to recover for 0.5–1 h in normal BME before further treatment. Cells were transferred to normal or low amino acid BME (stippled columns) for 10 h before glycine influx was measured. Low amino acid growth medium was prepared by omitting glutamine (2 mM), and glycine influx was taken as the initial uptake of 2-^{3}H-glycine in intracellular water, during a 5 min incubation at 37 °C (ref. 3). Different external concentrations of glycine were prepared by adding 2-^{3}H-glycine source to unlabelled glycine to give a specific activity of between 0.01 and 0.1 mCi mmol^{-1}. Radioactivity was determined by liquid scintillation counting of cell eluate, and quenching monitored by means of an external standard. Thin layer chromatography of cell extracts using *n*-butanol–water–acetic acid (12:5:3 by volume) solvent gave only a single peak which corresponded to glycine. Volume–surface area ratio of the cells was calculated assuming the cells were spherical. The number of observations are shown in each column. Means ± s.e. bars are given. Similar results were obtained in five experiments using cells grown on glass coverslips.

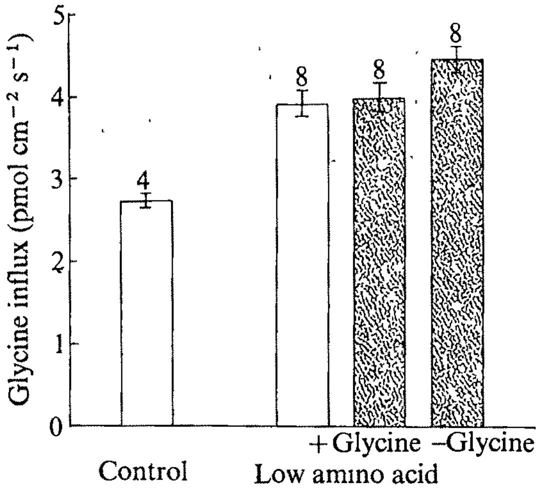

Fig. 2 The effect of altering intracellular amino acid concentration on the glycine transport-response of *Xenopus* cells to growth in low amino acid medium. Ordinate is glycine influx measured from 2 mM glycine* solution at 26 °C. Cells were placed into low amino acid growth medium at time zero. At intervals of 2 h thereafter some cells (stippled columns) were 'lysed'[6], refilled with either zero or 80 mM glycine and returned to the low amino acid growth medium. The response to extracellular amino acid concentration occurred whether intracellular concentration was high or low (Student's *t* test $P<0.001$). The number of observations are shown in each column. Values given are means ± s.e. bars.

It is probable that some cell membrane was lost during the enucleation procedure ('wrapped' around the nucleus). Loss of cell membrane was approximately 47%, a value sufficient to explain the loss of transport capacity in terms of carrier loss rather than carrier activity.

Incubation of enucleated cells in low amino acid BME caused a decrease rather than an increase in their glycine influx (Fig. 1). This may represent a secondary regulatory mechanism, an increase in the rate of catabolism of a labile carrier protein. This presupposes the continuous synthesis of protein directly involved in carrier-mediated active transport.

Specificity of cellular retinol-binding protein for compounds with vitamin A activity

THE importance of vitamin A (retinol) for normal growth and development of vertebrates is well established[1] but its mechanism(s) of action, except in vision, remains obscure. Retinol can influence differentiation of epithelial cells[2] and is required for normal development of the testis and for maintenance of pregnancy[3], suggesting a regulatory role resembling that of certain hormones in some aspects of its activity. The action of many steroid hormones is apparently mediated through specific cellular binding proteins[4]. We have found that rat tissues[5,6] and human[5] and rabbit lungs[7] contain a protein able to bind all-*trans*-retinol, the most potent vitamin A compound, with high affinity and specificity. In all species studied so far, this protein has the same apparent size (molecular weight 14,000, sedimenting in the 2S region on sucrose gradients) and seems to carry retinol as a non-covalently bound ligand *in vivo*[6,7]. It has a lower molecular weight and a different fluorescence excitation spectrum[6] than that reported for the intensively studied retinol binding protein of serum[8], demonstrating that we are dealing with a different protein. We have purified this cellular binding protein 1,000-fold from rat testes[6] and 600-fold from rabbit lung[7] and report here its specificity in binding various compounds exhibiting vitamin A activity *in vivo*.

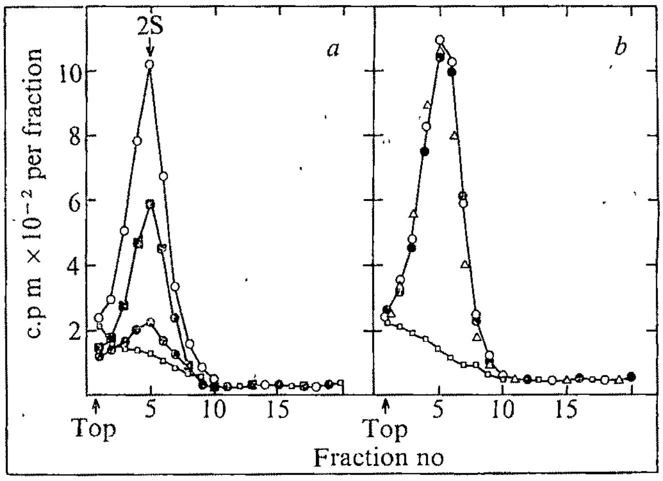

Fig. 1 Binding of all-*trans*-15-^{3}H-retinol (specific activity 1.25 Ci mmol^{-1}, New England Nuclear Corp.) to rat testis retinol-binding protein purified 1,000-fold. A sample (0.2 ml) of an 0.5-ml incubation mixture containing 10 μg of protein, 4×10^{-8} M all-*trans*-^{3}H-retinol with and without 8×10^{-6} M competitor, 0.05 M Tris-HCl, *p*H 7 6, was layered on a 5–20% sucrose gradient in 0.05 M Tris-HCl, *p*H 7.6 and centrifuged in a SW 50.1 rotor for 20h at 4 °C and 148,000*g*. Fractions of 0.25 ml were collected and radioactivity was determined. *a*· ○, ^{3}H-retinol only; ■, plus 9-*cis* retinol; ●, plus 13-*cis*-retinol; □, plus all-*trans*-retinol. *b*: ○, ^{3}H-retinol only; △, plus retinyl palmitate; ●, plus retinal; □, plus α-retinol.

Samples of the partially purified protein were incubated with radioactive all-*trans*-retinol in the absence and presence of excess unlabelled test compound and then subjected to sucrose gradient centrifugation. Retinol in aqueous solution adsorbed somewhat to glass and to the polyallomer centrifugation tubes and generally did not appear at the top of the gradient after centrifugation as would be expected for a non-adsorbed small molecule. Binding was indicated by a peak of radioactivity in the 2S region of the gradient. Gradients for some of the compounds tested are shown in Fig. 1. The results of all binding competition experiments are presented in Table 1 and expressed as percentage inhibition (percentage decrease) of binding of radioactive all-*trans*-retinol observed when the competitor was present in a 200-fold molar excess over the ^{3}H-retinol. The relatively large excess of competitor was used to detect compounds with low affinity for the binding protein. The actual numbers obtained are interpreted to indicate only the relative ability of the listed compounds to interact with the binding protein.

Of the *cis*-isomers tested, using the binding protein from both rat and rabbit, 13-*cis*-retinol was the most effective competitor although less effective than all-*trans*-retinol, while 9-*cis* and 9,13-di *cis*-retinol had significantly less but approximately equal abilities to compete, compared with all-*trans*-retinol. It is interesting that the ability of the *cis*-isomers to stimulate growth in the vitamin-A-deficient rat (last column, Table 1) followed the same pattern, with 13-*cis*-retinol the most effective, while 9-*cis*

Table 1 Percentage inhibition of binding of all-*trans*-^{3}H-retinol to protein by vitamin A active compounds

Compound*	Rat binding protein %	Rabbit binding protein %	*In vivo* activity (rat) (%)
All-*trans*-retinol	100	100	100
Cis-isomers			
13-*cis*-retinol	95	92	75 (ref.) 9)
9-*cis*-retinol	51	66	22 (ref. 9)
9,13-di *cis*-retinol	64	62	24 (ref. 9)
Ring isomers			
α-retinol	100	100	2 (ref. 10)
3-dehydroretinol (vitamin A_2)	100	100	40 (ref. 11)
C-15 modifications			
retinal	0	0	91 (ref. 10)
retinoic acid	0	0	100 (ref. 12)
retinyl acetate	0	0	100 (ref. 9)
retinyl palmitate	0	0	100 (ref. 13)

*Added in 200-fold molar excess over all-*trans*-^{3}H-retinol (8×10^{-8} M).

and 9,13-di *cis*-retinol had lower and approximately equal activities, compared with all-*trans*-retinol. These data suggest that the ability to interact with the cellular binding protein is one of the factors which determines whether a compound possesses vitamin A activity.

In contrast, both α-retinol and 3-dehydroretinol (Fig. 2) competed as well as all-*trans*-retinol in our binding assay, whereas their *in vivo* activities have been established to be 2% (ref. 10) and 40% (ref. 11), respectively, compared with all-*trans*-retinol. When administered to the rat, however, α-retinol is stored in the liver with high efficiency[10] and, at high doses, fully supports growth and development[14]. Goodman *et al.*[14] observed that α-retinol could not enter into the normal serum transport system and so delivery to target tissues is probably inefficient. Clamon *et al.*[15] have shown that when α-retinyl acetate is added directly to serum-free organ cultures of hamster trachea with keratinised squamous lesions induced by vitamin A deficiency, it is virtually as effective as all-*trans*-retinyl acetate in reversing the metaplasia. Apparently, the change in ring confirmation prevents the release of α-retinol from the liver to the serum transport system leading to a low *in vivo* activity, which does not necessarily reflect its potency in a target tissue or conflict with its demonstrated ability to interact with the tissue retinol binding protein (Fig. 1*b*). This sensitivity to ring conformation may also explain why 3-dehydroretinol exhibits less activity than all-*trans*-retinol *in vivo*[11].

Finally, the binding protein showed a stringent requirement for the alcohol function at C-15, as neither retinal, retinoic acid nor esters of the alcohol competed for binding (Fig. 1*b*). Since retinal can be reduced to retinol[16] *in vivo* and the esters hydrolysed to retinol[17], their biological activity may represent their conversion to all-*trans*-retinol, which is bound so effectively by the binding protein. Retinoic acid is not reduced to the alcohol *in vivo*[18] and although it reverses some of the lesions of vitamin A deficiency, it cannot prevent degeneration of the testes or maintain pregnancy in the rat[3]. It does not seem to act through the retinol-binding protein described here. We have found that several rat tissues contain a binding protein specific for retinoic acid and separable from that binding retinol[6]. This protein might be similar to that described in chick embryonic skin[19]. The action of retinoic acid may be mediated by its own binding protein.

Fig. 2 Chemical structures of all-*trans*-retinol, α-retinol and 3-dehydroretinol.

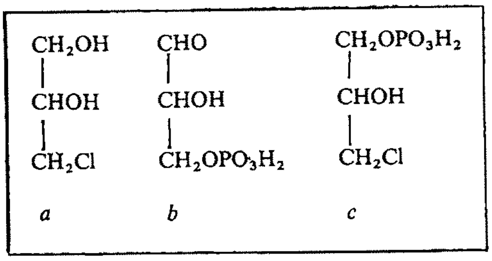
Identification of the biochemical lesion produced by α-chlorohydrin in spermatozoa

THE potential of α-chlorohydrin (3-chloro-1,2-propanediol; Fig. 1*a*) as an orally active reversible male antifertility agent has been demonstrated in the rat[1,2], ram[3] and boar[4]. Adverse side-effects, however, particularly in the monkey[5], have precluded human trials and for this reason, elucidation of the mechanism of action[6,7] of α-chlorohydrin is clearly important in order to develop less toxic yet more active antifertility analogues. Although high doses obstruct the lumen of the caput epididymis of the rat[2], the initial and primary contraceptive effect seems to be directly on spermatozoa within the cauda epididymis[8–11].

It has recently been shown in this laboratory that α-chlorohydrin is a potent inhibitor of glycolysis in ram spermatozoa both *in vitro* and *in vivo*. Thus, when washed ram spermatozoa (collected by electroejaculation) were incubated for 3 h with U-^{14}C-glucose (15 mM) or U-^{14}C-fructose (10 mM) in the presence of α-chlorohydrin (0.1 mM), no lactate accumulated, while oxygen uptake and the radioactivity recovered in the CO_2 were decreased to 50% of the control values. On the other hand, incubation of spermatozoa with U-^{14}C-pyruvate (5 mM) or U-^{14}C-lactate (5 mM) required α-chlorohydrin at a concentration of 10–100 mM to cause a 50% inhibition of oxygen uptake and oxidation of the substrates to CO_2. Inhibition of respiration caused by the oxidation of endogenous substrates, presumably lipid, was negligible until 100 mM α-chlorohydrin was added, when the oxygen consumption was decreased by only 20%. In another experiment the oxygen uptake of ram spermatozoal mid-pieces, which are essentially mitochondria[12], was monitored during incubation with either α-glycerophosphate (20 mM), succinate (20 mM) or pyruvate



$$\begin{array}{ccc} CH_2OH & CHO & CH_2OPO_3H_2 \\ | & | & | \\ CHOH & CHOH & CHOH \\ | & | & | \\ CH_2Cl & CH_2OPO_3H_2 & CH_2Cl \\ a & b & c \end{array}$$

Fig. 1 Structures of *a*, 3-chloro-1,2-propanediol; *b*, glyceraldehyde-3-phosphate; *c*, DL-1-chloro-1-deoxyglycerol-3-phosphate.

(20 mM)+malate (20 mM). The oxygen consumption, however, was not significantly affected by the addition of α-chlorohydrin at concentrations up to 100 mM.

From these results it is obvious that the glycolytic, rather than a subsequent oxidative pathway, is particularly vulnerable to α-chlorohydrin in spermatozoa. Positive identification of the inhibited site(s) was determined by measurement of the glycolytic intermediates following incubation of ram spermatozoa with fructose (15 mM) in the presence and absence of α-chlorohydrin (3 mM). It is clear from the 'cross-over' plot (Fig. 2) that the inhibited site is the formation of 3-phosphoglycerate (3 PGA) from glyceraldehyde-3-phosphate (GA3P; Fig. 1*b*). This step actually involves two enzymes, glyceraldehyde-3-phosphate dehydrogenase (GA3Pdh) and phosphoglycerate kinase. It is unlikely that the latter enzyme is inhibited because if it were, the intermediate compound, 1,3-diphosphoglycerate, would accumulate. This intermediate is extremely unstable and rapidly breaks down to 3PGA. Absence of the accumulation of 3PGA suggests that GA3Pdh is inhibited by α-chlorohydrin.

We investigated the direct effect of α-chlorohydrin on spermatozoal GA3Pdh. Enzyme extracts were prepared from washed ram spermatozoa by sonication for 5 min in sucrose (0.25 M) containing EDTA (10^{-3} M) and β-mercaptoethanol (10^{-3} M). Inclusion of α-chlorohydrin at concentrations as high as 300 mM in the reaction cuvette, however, had no effect on the activity of GA3Pdh or any of the other glycolytic enzymes assayed including; hexokinase, phosphofructokinase (PFK), aldolase, triosephosphate isomerase (TPI), phosphoglycerate kinase, pyruvate kinase or lactate dehydrogenase (LDH). From these results we conclude that α-chlorohydrin itself does not inhibit GA3Pdh directly.

The possibility of an indirect action due to a metabolite of α-chlorohydrin was tested by incubating washed spermatozoa for 3 h with fructose (15 mM) in the presence of a range of concentrations of the compound (0.03–300 mM). After incubation, the spermatozoa were separated by centrifugation and enzyme extracts of the cells prepared by sonication as described above. The results (Table 1*a*) showed that both GA3Pdh and TPI were severely inhibited at all concentrations of α-chlorohydrin, although the effect was greater on GA3Pdh than TPI. No other glycolytic enzymes were significantly affected except PFK and LDH which showed some inhibition at 300 mM α-chlorohydrin (not shown).

Similar studies have been carried out on ejaculated spermatozoa collected from rams which were injected for 4 d with α-chlorohydrin (25 mg per kg body weight daily). GA3Pdh activity was completely lost within 24 h of the first injection (Table 1*b*) and the activities of both TPI and aldolase were also severely inhibited compared with the preinjection levels. During the postinjection period the activities of these enzymes slowly returned to the preinjection levels and by 26 d this was essentially complete. The motility of the ejaculated spermatozoa was also monitored and always found to parallel the GA3Pdh activity.

The evidence, both *in vitro* and *in vivo*, is conclusive that aldolase, TPI and particularly GA3Pdh are severely inhibited by α-chlorohydrin, so that the flux of carbon through glycolysis ceases. Sufficient energy (from carbohydrate) is therefore not available to ejaculated spermatozoa for essential requirements, such as motility in the female tract and this may render them infertile.

Very recent experiments with the C_1 phosphorylated derivative of α-chlorohydrin (DL-1-chloro-1-deoxyglycerol-3-phosphate; Fig. 1*c*) suggest that this compound may be a

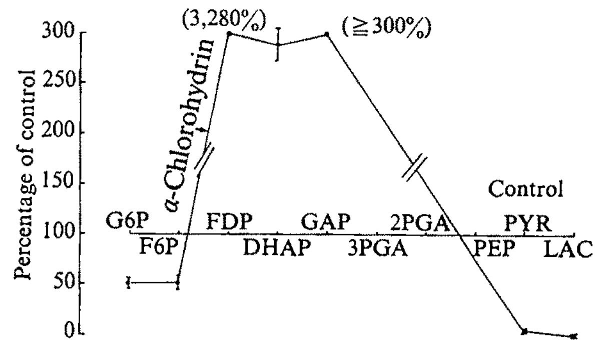


Fig. 2 'Cross-over' plot of the glycolytic intermediates of ram spermatozoa after incubation with fructose (15 mM) and α-chlorohydrin (3 mM). The glycolytic intermediates from the α-chlorohydrin treated spermatozoa are expressed as a percentage of the control values, which are arbitrarily called 100%. The phosphoglycerates and phosphoenol pyruvate were too low to be detected in both control and experimental spermatozoal extracts by the fluorometric methods used[13].

†Values are means of duplicate observations from a pool of 3 ram ejaculates. The differences between the duplicate observations are within 5%.

Values are means ± s.e.m. Five animals were involved in this experiment but all five ejaculates were not always available, the number of ejaculates used for each test is therefore shown in parentheses.

ND, Not detectable. Aldolase and GA3Pdh were assayed according to Wu and Racker[14] and TPI by the method of Beisenherz[15].

metabolic product of α-chlorohydrin which directly affects GA3Pdh, TPI and aldolase. Addition of DL-1-chloro-1-deoxyglycerol-3-phosphate (0.1 mM) severely inhibited the activity of GA3Pdh (53%) in the reaction cuvette containing spermatozoal sonicate. One hundred times that concentration of inhibitor was required for significant inhibition of TPI and aldolase. We suggest that α-chlorohydrin is phosphorylated on entry into the spermatozoa. The phosphorylated compound may then act as a competitive inhibitor of GA3Pdh because of its structural similarity to the normal substrate of the enzyme, glyceraldehyde-3-phosphate. Further investigations of this hypothesis are presently under way.

We thank Professor C. W. Emmens for his interest and advice and the Upjohn Company of Kalamazoo, Michigan, for the gift of α-chlorohydrin. The investigation has received financial support from the World Health Organization.

Localisation of plutonium in mouse testes

THE plutonium isotope ^{239}Pu is a known carcinogen but its ability to produce genetic damage has not been so well investigated. The radionuclide is found in gonads after intravenous injection into humans[1] and after administration to animals by various routes[2]. Retention of ^{239}Pu in the gonads is prolonged and the genetic effects there have been estimated on the basis of average dose in the gonads[3]. Inhomogeneity of distribution of plutonium within gonads has, however, been noted[4] giving rise to the possibility that some cells may receive a greater radiation dose than others. No investigations of the effects of this inhomogeneity upon dose-rate to the cells involved in gametogenesis have been reported. Here we report briefly that a non-uniform distribution of ^{239}Pu in the testis results in increased radiation of the spermatogonial stem-cells.

Groups of 12-week-old male CBA mice were killed 4 or 12 weeks after intravenous injection of ^{239}Pu citrate. The plutonium in each right testis was measured radiochemically (Table 1). Autoradiographs prepared from 6-μm sections of frozen left testes showed that some 90% of the plutonium seemed to be deposited within the intertubular spaces and in the peritubular tissue immediately surrounding them.

Table 1 Radiochemical analysis of the right testis of CBA mice following intravenous injection of ^{239}Pu in 1% trisodium citrate solution

Weeks after injection	4	12
Number of testes	5	6
Testis mass (mg, mean ± s.e.)	73±1	67±4
Plutonium (pCi, mean ± s.e.)	20±3	23±2
Plutonium (pCi g^{-1}, mean ± s.e.)	280±45	350±38
Average dose rate (rad d^{-1}, mean ± s.e.)	0.072±0.012	0.092±0.010

A mean activity of 88 nCi ^{239}Pu was injected into each mouse; 3.2 μCi per kg body mass.

A total of 12,000 α tracks were counted in more than 700 randomly selected fields from 58 sections.

The α tracks could be categorised into: those which lay entirely above the intertubular spaces (47%); those which lay above the peritubular membrane or above the adjoining 10-μm layer of cells containing the spermatogonial stem cells (42%); and those which lay entirely within the peritubular membranes but excluding those in group 2 (11%).

On the assumption that the testis consists of a close-packed series of cylinders of uniform diameter (experimentally determined mean value =206 μm) it was calculated that the 10-μm shell of tissue surrounding each tubule and containing the spermatogonial stem-cells, constituted 17% of the whole testis mass. It was then assumed that the spermatogonial stem-cells were randomly distributed in these 10-μm peritubular shells and a dose inhomogeneity factor N (ref. 5) was calculated:

$$N = \frac{\text{average dose to spermatogonial stem-cells}}{\text{average dose to whole testis}}$$

$$= \frac{\text{fraction of all } \alpha \text{ tracks in group 2}}{\text{fraction of testis mass in 10-}\mu\text{m peritubular shells}}$$

$$= \frac{0.42}{0.17} = 2.5$$

Therefore, from the data given in Table 1, dose rates to spermatogonial stem-cells in our experiment were 0.18 and 0.23 rad d^{-1} at 4 and 12 weeks respectively. A value $N=2$ was also calculated directly from the model system assuming random distribution of ^{239}Pu in the intertubular spaces and taking into account the transfer of energy along the path of each α particle (M. C. Thorne, personal communication).

Our results show that for mice the radiation dose rate to the spermatogonial stem-cells is greater by a factor of 2–2.5 than the average for the testis as a whole calculated directly from the total amount of ^{239}Pu deposited in the gland. This implies that the genetic effects may be proportionately greater. The validity of the factor N as calculated and the biological effectiveness of α particles relative to other radiations are matters now undergoing cytological investigation (A. G. Searle, personal communication). It would also be important to establish comparable values for ovaries. Much more work is required to decide on appropriate values for men.

Modification of drug biotransformation by vitamin C in man

VITAMIN C (ascorbic acid) is taken by many individuals in very large doses and there has been some concern about possible adverse effects of such regimens. It has been found that vitamin C is metabolised in part to ascorbic acid sulphate in man[1]. Sulphate formation is also an important pathway for the biotransformation of phenolic drugs[2]. This pathway is, however, of limited capacity in man[3] (and in many species of animals) and is therefore subject to saturation and competitive inhibition. Such mutual inhibition by two or more substrates is caused by the limited availability of sulphate and can be overcome by concomitant administration of sulphate or a sulphate donor[3]. Studies in man have demonstrated competitive inhibition of sulphate formation between acetaminophen and salicylamide, two widely used analgesics and antipyretics, and the prevention of this inhibition by concomitant administration of the sulphate donor L-cysteine[4]. We now report the results of a study which shows that concomitant administration of vitamin C and salicylamide causes a decrease in the conversion of the latter to salicylamide sulphate.

The results of the study are summarised in Table 1. Recovery of total salicylamide (that is, the sum of all urinary excretion products of the drug) was essentially quantitative (95% of the dose) and was not affected by vitamin C. The fraction of the dose excreted as salicylamide sulphate was significantly decreased and that excreted as salicylamide glucuronide was increased by concomitant administration of vitamin C. Eight of the ten subjects showed this decrease in salicylamide sulphate output; the effect was particularly pronounced in subjects C, H, I and L. There was a corresponding, statistically significant change in the average maximum excretion rates of the metabolites: 0.562 and 0.513 mg salicylamide equivalent per min for the sulphate in the control and vitamin C experiments, respectively ($P < 0.02$ by paired t test), and 0.715 and 0.824 mg salicylamide equivalent per min for the glucuronide in the control and vitamin C experiments, respectively ($P < 0.005$ by paired t test). The vitamin had no statistically significant effect on the pH and flow rate of urine.

Previous studies have shown that the extent to which salicylamide is converted to salicylamide sulphate in man is decreased with increasing dose, increased by administration of a sulphate donor and increased by decreasing the rate of absorption of the drug[3]. Vitamin C may decrease the rate of absorption of salicylamide because the vitamin inhibits gastric emptying in man[5]. Thus, the vitamin may cause a decrease in salicylamide sulphate formation by one mechanism and an increase by another mechanism, so that a typical dose–response relationship for the effect of vitamin C on sulphate formation should not be expected. It is likely that there is an optimum dose of vitamin C for maximum reduction of salicylamide sulphate formation, a dose at which the inhibitory effect of the vitamin on salicylamide absorption is relatively less pronounced than its effect on sulphate formation. This optimum dose probably differs between individuals and may differ also as a function of dosage form (solution, tablets, and so on) and drug (that is, drugs other than salicylamide which are also subject to sulphate formation). It is also likely that individuals differ in their capacity for vitamin C absorption (the vitamin is absorbed by a specialised saturable process[6]) and in the rate at which endogenous sulphate is available for conjugation with a substrate such as salicylamide. All of these variables may account for the interindividual variations in the effect of vitamin C on the formation of salicylamide sulphate as found in this study.

A number of drugs are extensively conjugated with sulphate (and thereby inactivated) in the first pass through the intestinal tissues and liver following oral administration. One such drug is isoprenaline (isoproterenol) which is used widely for the treatment of asthma and certain cardiac diseases. The recommended

Ten healthy male volunteers 25–47 yr old, capable by education and experience to give their informed consent (research assistants and associates), participated in the study. They were instructed not to take any drugs or vitamins for at least one week before and during the study. They fasted overnight, emptied their bladder in the morning and took 100 ml of water or 2 g of vitamin C in 100 ml water. One hour later, they collected their urine and took 150 mg salicylamide alone or with 1 g vitamin C, both dissolved in 100 ml water. No food or drink other than water was permitted for the following 2 h. Urine was collected at 0.5, 1, 1.5 and 2 h after salicylamide administration and at convenient times thereafter for a total of 24 h, each time followed by 100 ml water to assure adequate urine flow. Five of the subjects took salicylamide with vitamin C, whereas the other five took salicylamide only. At least 1 week later, the former took salicylamide alone, whereas the latter took it with vitamin C. The urine samples were analysed for total salicylamide and its metabolites (salicylamide sulphate, salicylamide glucuronide and gentisamide) as described previously[3]. Blank values obtained from the 1 h urine sample collected before salicylamide administration were used to correct the analytical results; blank values from urine obtained after administration of the initial 2-g dose of vitamin C did not differ from those obtained without prior ingestion of the vitamin. Several urine samples obtained after administration of salicylamide alone were diluted with an equal volume of urine either from unmedicated subjects or from subjects taking vitamin C; there were no differences in analytical results, showing that the vitamin and its metabolites did not interfere with the analysis of salicylamide and its metabolites. Some urine samples obtained after ingestion of salicylamide alone and after ingestion of salicylamide with vitamin C were analysed immediately after collection and again after 10 d of storage in a refrigerator. These analyses yielded essentially identical results, thereby ruling out a possible effect of ascorbic acid or its metabolites on the stability of the salicylamide metabolites.

*2 g taken 1 h before salicylamide and 1 g taken concomitantly.

†150 mg salicylamide dissolved in 100 ml water.

‡Paired t test.

oral dose of this drug is about 100–1,000 times larger than its intravenous dose[7], reflecting largely its extensive inactivation by biotransformation during absorption. It has been predicted[8] and demonstrated in dogs[9] that salicylamide can markedly inhibit this inactivation. Following introduction of isoprenaline into the intestinal lumen of anaesthetised dogs, only 3.6% of the total amount absorbed was unmetabolised drug; 68% was isoprenaline sulphate. When isoprenaline was given with salicylamide, 73.7% of the absorbed amount was unmetabolised isoprenaline and only 3.3% was in the form of the sulphate conjugate, on the average. Similar effects may occur when vitamin C is taken with drugs which ordinarily undergo extensive conjugation with sulphate during their initial passage across the intestinal mucosa and through the liver. This could result in a significant potentiation in the pharmacological activity of drugs so affected.

Tryptophan pyrrolase activity regulation in *Drosophila:* role of an isoacceptor tRNA unsettled

TRYPTOPHAN pyrrolase is a key enzyme in the biosynthetic pathway leading to the ommochromes[1]. In wild-type flies of *D. melanogaster* or *D. hydei*, tryptophan is converted by this enzyme into *N*-formyl kynurenine, which is hydrolysed to formic acid and kynurenine. Further metabolism of kynurenine results in the deposition of the yellow-brown pigments in the eyes of these insects. Tryptophan pyrrolase activity, however, is lacking or greatly reduced in freshly prepared homogenates of living imagines of the vermilion mutants of *D. melanogaster*[1,2,3] or *D. hydei* (Table 1). Finding a stimulation of tryptophan pyrrolase activity in homogenates of *D. melanogaster* vermilion flies by RNase T_1 treatment and an inhibition of this activity by wild-type tRNA preparations or by an isoaccepting tyrosine tRNA ($tRNA_2^{Tyr}$) led Jacobson[4,5] to suggest the implication of this specific isoaccepting tRNA in the regulation of tryptophan pyrrolase activity and in the mechanism of genetic suppression of the vermilion mutant. Because of the importance of these conclusions and their bearing on the general understanding of the basic molecular mechanisms of enzyme regulation and suppression in eukaryotes, we reinvestigated the entire system including the assay procedure.

Tryptophan pyrrolase activity is assayed on the basis of the amount of kynurenine produced from tryptophan in homogenates of the respective insect tissues. This assay, however, is usually hampered by microbial contamination and the lack of a good technique for the direct determination of the kynurenine produced in the assay mixture. Avoiding the unreliable and troublesome diazotation reaction of Bratton and Marshall[6], we identified kynurenine by its R_f value and typical light-blue fluorescence after thin-layer chromatography on cellulose powder, and quantitated kynurenine on the basis of its extinction at 360 nm. To eliminate microbial contamination, penicillin and streptomycin were included in the assay mixture.

All our attempts failed to induce tryptophan pyrrolase activity in freshly prepared homogenates of *D. melanogaster* or *D. hydei* vermilion flies by RNase T_1 or RNase A treatment (Table 1) following exactly the procedure published[4]. This failure cannot be attributed to either lack of RNase activity or a difference in strain: the vermilion mutant was suppressable with the *D. melanogaster* vermilion suppressor *su*(s)[2], and RNase activity stays very high for several hours in our assay system.

Tryptophan pyrrolase activity can be stimulated to almost wild-type activity levels when homogenising vermilion flies in the presence of 0.02 M EDTA, a standard ingredient in RNase assay mixtures. To prove that the substance produced in the EDTA activated vermilion mutants is kynurenine, 2-^{14}C-tryptophan was added to our standard tryptophan pyrrolase assay mixture. The resulting product was purified to constant specific radioactivity, and the identity of this radioactive compound with L-kynurenine was demonstrated by thin layer chromatography on cellulose powder in three different solvent systems. In the presence of EDTA, tryptophan pyrrolase activity is generally stimulated in homogenates of wild-type and vermilion mutant strains of *D. melanogaster* as well as *D. hydei*, independent of the developmental stage of the respective organisms (Table 1).

The tryptophan pyrrolase activity stimulated by EDTA in the vermilion homogenates could not be blocked by tRNA preparations of the respective wild strains. The EDTA stimulated tryptophan pyrrolase activity of *D. melanogaster* vermilion imagines was separated from the EDTA by passing the homogenate through a Sephadex G-75 column. This activity could also not be blocked by the addition of a purified tRNA preparation of wild-type *D. melanogaster* imagines (Table 1).

Table 1 shows an additivity of the normal and EDTA stimulated tryptophan pyrrolase activity, from which it may be

Table 1

Organism and treatment*	Kynurenine (μg, average produced by 100 mg of fresh tissue) Without EDTA	With EDTA	EDTA-activated, tRNA added
D. melanogaster wild strain, imagines	46	70	—
D. melanogaster vermilion, imagines	ND	32	18
D. melanogaster vermilion, imagines, RNase T_1	ND	36	—
D. melanogaster vermilion, imagines, RNase A	ND	35	—
D. melanogaster vermilion, IIIrd instar larvae	ND	26	—

D. hydei vermilion, imagines	ND	14	—

*Living organisms (500 mg) were homogenised in 5.5 ml Tris-HCl (0.01 M, *p*H 7.5) supplemented with 3 mg mercaptoethanol, 4 mg ascorbate, 4.3 mg streptomycin and 2.15 mg penicillin Following centrifugation, either 1 ml tryptophan solution (5 mg ml^{-1} homogenisation medium) or 1 ml homogenisation medium was added to 1.5 ml supernatant. Incubation was for 3 h at 37 °C Ethanol was added to a final concentration of 70% and kynurenine production was determined as in the text. Reproducibility of kynurenine determination in duplicate experiments was better than 95%. For tryptophan pyrrolase activity stimulation the homogenisation medium was made 0.02 M in EDTA. Purified tRNA of *D. melanogaster* wild strain imagines (10 μg ml^{-1}), RNase T_1 (up to 1,500 U) and RNase A (4 units) were present in the reaction mixture where indicated.

ND, not detectable.

inferred that the tryptophan pyrrolase activity stimulated by EDTA possibly stems from an enzyme (perhaps a peroxidase) other than the original tryptophan pyrrolase molecule.

On the basis of our results it seems that the elegant idea of enzyme activity modulation in eukaryotes by varying proportions of specific isoacceptor tRNA molecules[4,5,7] still needs substantiation. In addition, the molecular basis of the mechanism of genetic suppression in eukaryotes[7,8] needs further elucidation.

Effects of cordycepin and cordycepintriphosphate on polyadenylic and ribonucleic acid-synthesising enzymes from eukaryotes

GENETIC information encoded in the nuclear DNA of a eukaryotic cell is selectively transcribed into an array of nuclear RNA molecules heterogeneous in size, base sequence and half-life. The α-amanitin-sensitive, DNA-dependent RNA polymerase isolated from nucleoplasm is thought to catalyse the transcription of heterogeneous nuclear RNAs (HnRNA). While in the nucleus, the length of HnRNAs is modified in two ways: first, HnRNAs are lengthened by addition of a poly(A) sequence. The ATP–polynucleotidylexotransferase isolated and purified from several eukaryotic tissues is presumed to catalyse the sequential addition of AMP moieties to the 3′ terminus of the HnRNA. Secondly, HnRNAs bearing poly(A) tails are thought to be shortened by cleavage of a portion of the nucleotide sequence at the 5′ terminus and the remainder transported to the cytoplasm. After association with ribosomal subunits, the processed transcripts form polysomes and function as mRNAs in the translation of specific polypeptides. Inferences as to the processing of HnRNA to give rise to mRNA are drawn from experiments using cordycepin (3′-deoxyadenosine) as an inhibitor of RNA synthesis[1-2]. Interpretation of many of these experiments rests on the assumption that the cordycepin selectively inhibits the addition of polyadenylic acid to HnRNA[4-6]. On the other hand, Klenow[7] has shown that cordycepin is phosphorylated to 3′-dATP by Erlich ascites tumour cells, and using a bacterial DNA-dependent RNA polymerase, Shigeura and Gordon[8] demonstrated inhibition of *in vitro* RNA synthesis by 3′dATP. They postulated that the mechanism of inhibition involved incorporation of the 3′-dATP into the growing chain of RNA with subsequent failure to provide a 3′-hydroxyl for the next incoming nucleosidetriphosphate to terminate elongation prematurely.

To directly determine if the mode of cordycepin inhibition of mRNA synthesis was on poly(A) addition to HnRNA or on the synthesis of HnRNA *per se* we tested the effect of cordycepin and 3′-dATP on a eukaryotic α-amanitin-sensitive, RNA polymerase and on two eukaryotic ATP–polynucleotidylexotransferases. The RNA polymerase was specifically inhibited by the 3′-dATP. The poly(A)-synthesising enzymes were no more sensitive to 3′-dATP than to 2′-dATP (the naturally occurring DNA precursor). All activities were refractory to low levels of cordycepin.

Table 1 Effect of cordycepin and 3′-dATP on poly(A) synthesis by HeLa ATP–polynucleotidylexotransferase

Drug	Concentration (mM)	Specific activity (nmol AMP mg^{-1})	Inhibition (%)
None	0	466	0
Cordycepin	3.6	277	41
Cordycepin	15.4	185	60
2′-d Adenosine	3.6	144	69
2′-d Adenosine	15.4	160	66
3′-dATP	0.22	356	24
3′-dATP	0.44	188	60
2′-dATP	0.22	331	29
2′-dATP	0.44	208	56

ATP–polynucleotidylexotransferase was prepared from HeLa S_3 cells by the method of Mans and Stein[14]. After step-wise elution from DEAE–cellulose the enzyme was purified further on a 2–20% glycerol gradient in 2.5 mM Tris (*p*H 8), 1 mM 2-mercaptoethanol and 100 mM $(NH_4)_2SO_4$ at 27,000 r.p.m. in an SW27 rotor at 4 °C for 68 h. Poly(A)-synthesising activity was assayed as described previously[15] with 1.7 A_{260} ml^{-1} *E. coli* tRNA as primer and the indicated drug.

To test directly the inferred inhibition of poly(A) synthesis by cordycepin and 3′-dATP we examined their effects on poly(A) synthesis by HeLa ATP–polynucleotidylexotransferase[14]. Cordycepin, at 15 times the level of substrate, inhibited the poly(A)-synthesising activity by only 60% (Table 1) and was no more potent than 2′-deoxyadenosine (2′-dA). The phosphorylated derivative, 3′-dATP, inhibited the HeLa exotransferase by only 24% at 0.22 mM and was no more potent than 2′-dATP. Therefore, *in vitro* poly(A) synthesis was insensitive to cordycepin and no more sensitive to 3′-dATP than to the naturally occurring DNA precursor, 2′-dATP.

The phosphorylated derivative, 3′-dATP, specifically inhibited the eukaryotic RNA polymerase to the same extent and with the same specificity as seen with the bacterial RNA polymerase (Fig. 1). Note that addition of 3′-dATP during the course of the reaction immediately halted AMP incorporation (Fig. 1*b*), consistent with the termination of elongating chains by the incorporation of 3′-dATP. The sensitivity of the eukaryotic DNA-dependent RNA polymerase to cordycepin was as slight and non-specific as that of the eukaryotic poly(A)-synthesising activity; no inhibition was observed with either 13.4 mM 3′-dA or 2′-dA.

The lack of specificity of inhibition of poly(A) synthesis in contrast to the strict specificity of inhibition of RNA synthesis by 3′-dATP is explicable. Poly(A) addition to an RNA primer and RNA synthesis on a DNA template proceed by different mechanisms of nucleotide incorporation. In poly(A) synthesis the RNA provides a 3′-hydroxyl terminus for its elongation as poly(A). Substrate specificity of the exotransferase is restricted to ATP and is conferred by the protein alone. In the RNA

Table 2 Effect of 3′-dATP on eukaryotic RNA polymerase utilisation of poly(dAT)

System	Inhibition of incorporation from 8-^{14}C-ATP (%)	Inhibition of incorporation from 2-^{14}C-UTP (%)
Complete less UTP	97	—
Complete less ATP	—	86
Complete plus 3′-dATP (0 11 mM)	95	96
Complete plus 2′-dATP (0 33 mM)	—	3

The complete reaction mixture was as described by Mans[18] except 0.52 A_{260} ml^{-1} poly(dAT) was substituted for DNA, and CTP and GTP were omitted.

Table 3 Effect of cordycepin and 3′-dATP on poly(A) synthesis by maize ATP–polynucleotidylexotransferase on several primers

Primer	Inhibition (%) of ^{14}C-AMP incorporation with			
	3′-dA(15.4 mM)	2′-dA(15.4 mM)	3′-dATP(0.22 mM)	2′-dATP(0.22 mM)
tRNA	48	36	69	49
Heated DNA	—	—	43	48
Poly(dT)^{10}	77	71	65	74
Poly(dT)	—	—	71	79

ATP–polynucleotidylexotransferase (fraction 5) was prepared from maize seedlings and assayed as described by Mans and Huff[15] except 0.44 A_{260} ml^{-1} of indicated primer and drug were added. The specific activity (nmol AMP incorporated per mg enzyme protein in 90 min at 30 °C) was 2,630, 3,050, 1,730 and 750 for the tRNA, DNA, poly(dT)$_{10}$ and poly(dT)-primed reactions, respectively.

polymerase reaction the DNA template serves to hydrogen bond each of the four nucleosidetriphosphates in proper sequence before their polymerisation by the enzyme. Substrate specificity of the RNA polymerase is extended to several ribonucleotides and is conferred by both the template and the enzyme. Both 2′-dATP and 3′-dATP have the adenine moiety required for exotransferase substrate specificity and compete effectively with ATP in binding to the enzyme. Although both 2′-dATP and 3′-dATP compete with ATP in hydrogen-bonding to the template only, the 3′-dATP has the 2′-hydroxyl in common with the natural substrates utilised by the RNA polymerase. Therefore, only 3′-dATP is incorporated into the RNA chain to subsequently terminate elongation.

Use of a deoxyoligomer as a template by the eukaryotic RNA polymerase was demonstrated by the requirement of ATP for ^{14}C-UMP incorporation and UTP for ^{14}C-AMP incorporation in the presence of the alternating copolymer, poly(dAT) (Table 2). Inhibition of ^{14}C-UMP as well as ^{14}C-AMP incorporation by 3′-dATP but not by 2′-dATP is again consistent with the known substrate specificity of the enzyme (for 2′ hydroxyl) mediated by base pairing (A–T) with the template. The homopolymer, poly(dT), also serves as a template for AMP incorporation that is sensitive to 3′-dATP but not to 2′-dATP (data not shown). Incorporation with either polymer is refractory to actinomycin D at 10 µg ml^{-1} anticipated with templates lacking guanosine residues.

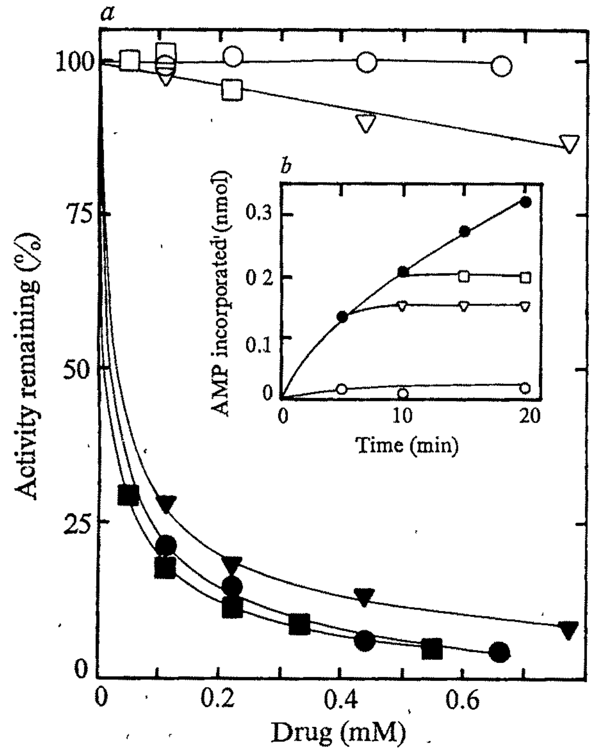

Fig. 1 *In vitro* effects of 3′-dATP on RNA synthesis. RNA polymerase (fraction 4) was prepared from *E. coli* K-12 and assayed on heated calf thymus DNA at 37 °C by the procedure of Burgess[17] (□, ■). RNA polymerase II (fraction 4) was prepared from maize seedlings and assayed on heated calf thymus DNA at 30 °C as described by Mans[18] with either 8-^{14}C-ATP (○, ●) or 2-^{14}C-UTP (▽, ▼) as labelled substrates. Either 3′-dATP (closed symbols) or 2′-dATP (open symbols) was added before incubation Nucleotide incorporated was determined as acid-insoluble radioactivity on filter paper disks[18]. No activity was detected on omission of enzyme or DNA or on addition of actinomycin D (10 µg ml^{-1}) to either enzyme assay or addition of α-amanitin (50 µg ml^{-1}) to the maize enzyme. The insert shows the rate of ^{14}C-AMP incorporation by the maize enzyme on addition of 3′-dATP (0.22 mM) after 0.5 min (○), 5.5 min (▽), 10.5 min (□) and no addition (●) incubation at 30 °C. Without drug the *E. coli* RNA polymerase incorporated 60 nmol AMP per mg protein in 10 min at 37 °C and the maize RNA polymerase incorporated 30 nmol AMP per mg protein in 10 min at 30 °C. HeLa S_3 cells were grown exponentially in suspension culture at 37 °C in Eagle's MEM supplemented with 3.5% each of calf and foetal calf serum[9]. At 5×10^6 cells ml^{-1}, 1 l of the cell culture was centrifuged (200*g* for 15 min at 37 °C). The packed cells were resuspended in 100 ml of the above medium containing 0.5 mg ml^{-1} cordycepin at 37 °C and incubated with stirring at 37 °C for 1 h. The 3′-dATP was isolated from the acid-soluble fraction by modification of the procedures of Klenow[7] and Shigeura and Gordon[8]. The cells were harvested by centrifugation at 0 °C and immediately resuspended in 3 ml 5% $HClO_4$ at 0 °C. After centrifugation the pellet was re-extracted with 5% $HClO_4$ at 0 °C and the combined supernantant fluids adjusted to *p*H 6 with M KOH. To oxidise the ribonucleotides, 0.56 ml 0.25 M $NaIO_4$ was added to 9.8 ml supernatant fluid at 23 °C for 1 h (ref. 10). After cooling the mixture to 0 °C, 0.1 ml cyclohexylamine was added and the *p*H adjusted to 6.4 with acetic acid. The mixture was adsorbed to activated charcoal and the deoxynucleotides eluted with ethanol–pyridine–H_2O (50:5:45). The ethanol and pyridine were removed by evaporation and the remaining aqueous phase (3.7 ml) was applied to a Dowex 1-formate column (0.6×23 cm). The nucleotides were eluted with a 440 ml linear gradient of 0–2 M NH_4COOH (*p*H 4.5) at 11 ml h^{-1}. Nucleosidetriphosphates, lesser amounts of mono- and diphosphonucleotides were eluted in discrete peaks from the column with the NH_4COOH gradient analogous to the elution pattern observed by Klenow[7] for Erlich ascities tumour cells. On pooling the fractions eluting as nucleosidetriphosphates (300 through 350 ml), 43.0 A_{260} units were obtained of the 420 A_{260} units applied to the column. Fractions containing the putative 3′-dATP were pooled, the NH_4COOH removed by chromatography on Dowex 50 (hydrogen from 2.4×11 cm) and the ultraviolet-adsorbing material eluted with water was concentrated by lyophilisation. Most of the product (94.4%) was resistant to oxidation with $NaIO_4$, followed spectrophotometrically by the method of Dixon and Lipkin[11], as expected of a deoxynucleotide. The ultraviolet adsorption spectrum of the product was characteristic of adenine ($A_{280}/A_{260} = 0.18$) at both acid and alkaline *p*H. 2.02 mol of acid-labile phosphorus was present per mole of adenine as determined by the method of Fisk and Subbarow[12] indicating that the product was a nucleosidetriphosphate. An anthrone derivative of the product was a nucleosidetriphosphate. An anthrone derivative of the product exhibited an absorption spectrum characteristic of 3′-dATP (ref. 13) similar to that of cordycepin and distinct from that of the anthrone derivatives of ATP or 2′-dATP. Finally, the sensitivity (91% inhibition at 22 mM) of DNA-dependent RNA polymerase from *E. coli* to the isolated product was equivalent to that exhibited by 3′-dATP on RNA polymerase from *Micrococcus lysodeikticus*[8]. The enzyme was insensitive to the naturally occurring 2′-dATP.

To demonstrate that specificity of inhibition by the phosphorylated derivative of cordycepin requires a template, we utilised the ATP–polynucleotidylexotransferase from maize seedlings. This enzyme catalyses poly(A) synthesis on single-stranded DNA as well as on RNA primers[15-16]. The specificity of inhibition by 3′-dATP observed when heated calf thymus DNA was used as a template in the RNA polymerase reaction (Fig. 1) was lost when the DNA was used as a primer in the exotransferase reaction (Table 3). The inhibitor specificity was not restored with poly(dT), as expected if the deoxyoligomers were used as primers and not as templates for poly(A) synthesis[15]. Analogous to the HeLa enzyme, poly(A) synthesis on tRNA by the maize enzyme was inhibited about 50% by either 3′-dATP or 2′-dATP at 0.22 mM.

Our *in vitro* results show that cordycepin *per se* has no effect on poly(A) or RNA synthesis unless in great excess of substrate concentrations. As in ascites tumour cells the drug is phosphorylated to 3′-dATP by HeLa cells. The lack of specificity for inhibition of two eukaryotic exotransferases by 3′-dATP renders the postulated *in vivo* inhibition of poly(A) addition to HnRNA unlikely (assuming ATP–polynucleotidylexotransferase catalyses *in vivo* poly(A) addition to HnRNA). The differential effect of cordycepin on HnRNA and mRNA synthesis *in vivo* may be better interpreted in terms of the preferential inhibition of HnRNA synthesis on dT-rich templates by 3′-dATP and subsequent limitation of RNA primer for poly(A) addition. The transcription of dT-rich templates would be consistent with HnRNA synthesis with low levels of actinomycin D *in vivo*. The recent finding of oligo(A) sequences in some HeLa HnRNAs (ref. 6) indicates that poly(dT) sequences are transcribed by eukaryotic RNA polymerase *in vivo*.

Different ultraviolet DNA endonuclease activity in human cells

THE first step of the model of the excision repair mechanism for ultraviolet-irradiated DNA is the incision of the DNA adjacent to the pyrimidine dimer by an endonuclease (ultraviolet endonuclease)[1]. Such endonucleases have been purified from *M. luteus*[2] and T4-infected *E. coli*[3] and partially purified from uninfected *E. coli*[4]. Human cells also perform excision-repair of ultraviolet-irradiated DNA[5] and ultraviolet endonuclease activity has been identified in extracts of HeLa cells[6,7] and human fibroblasts[7]. An ultraviolet endonuclease has been purified from rat liver[8]. But it has not been proved that any of these enzymes are true repair endonucleases, for the proof of an enzyme's role in cellular metabolism rests on analysis of its activity in mutants[4]. Cells from patients with xeroderma pigmentosum (XP) seem to be excision-repair defective mutants[1] and have been postulated to lack the ultraviolet endonuclease activity necessary to initiate repair[9].

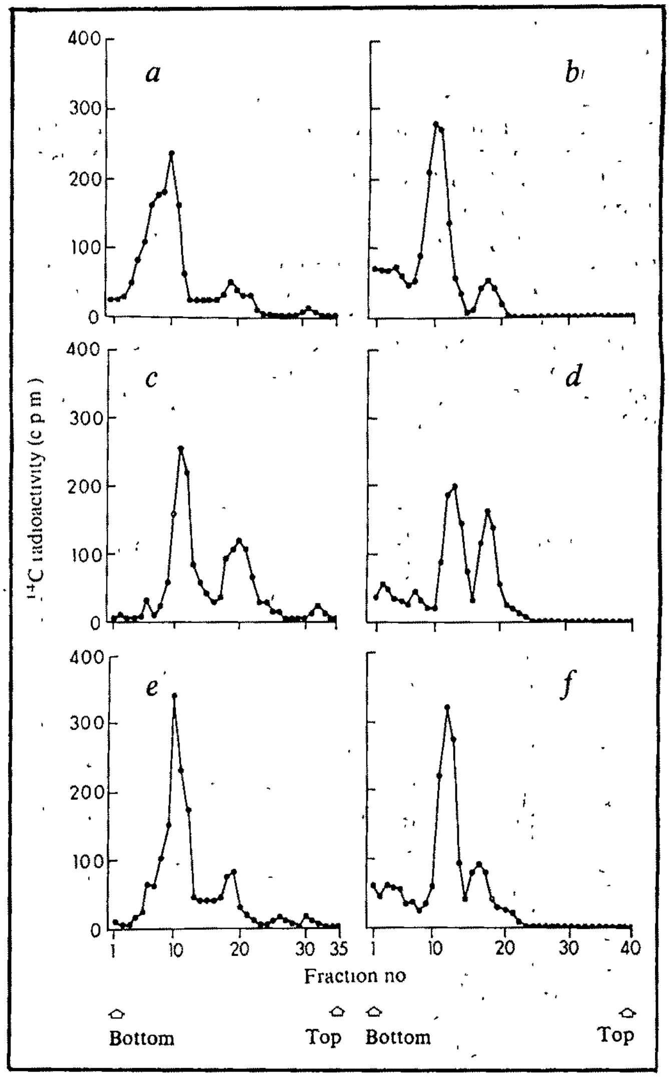

Fig. 1 Analysis of PM II superhelical DNA by sedimentation velocity centrifugation. Gradients *a* and *b* are profiles of 2-min ultraviolet-irradiated PM II DNA analysed by alkaline (*a*) and neutral (*b*) sedimentation velocity gradients. For alkaline gradients PM II DNA (0.1 μg) in a volume of 120 μl was layered on top of 4.0 ml of a 5–20% sucrose gradient, 0.001 M EDTA, 0.02% SDS, *p*H 13.0, with a 0.3-ml saturated caesium chloride cushion. Centrifugation was for 2.5 h at 40,000 r.p.m. in an SW 50L rotor in a Beckman ultracentrifuge (L2-65B). Neutral gradients contained the same amount of DNA layered on 3.0 ml of a 1.50 density caesium chloride solution, buffered with 0.01 M HEPES-KOH, *p*H 7.0, 0.001 M EDTA, overlayed with light mineral oil and centrifuged in the same rotor at 45,000 r.p.m. for 2.75 h. *c* and *d* are alkaline (*c*) and neutral (*d*) gradients of 2-min ultraviolet-irradiated PM II DNA incubated with HeLa cell enzyme preparation of approximately 2×10^5 cells under conditions identical to those described by Brent[6] in a volume of 120 μl. The reaction mixture was incubated for 20 min at 37 °C, chilled in ice, and then layered on top of alkaline and neutral gradients. Gradients (*e*) and (*f*) are the profiles of ultraviolet-irradiated PM II DNA incubated with the cell preparation of 2×10^5 XP skin fibroblasts (CRL-1200) and then centrifuged under alkaline (*e*) and neutral (*f*) conditions. All gradients were collected by the method of Carrier and Setlow[16] and counted in toluene–POPOP. Direction of sedimentation is from right to left. Ninety per cent of the applied radioactivity was recovered and all of it was under the two peaks.

Four genetic complementation groups have been identified among XP cells with rates of repair synthesis after ultraviolet irradiation that vary from 1% to 55% of control[10]. Using skin fibroblasts of each group, we have assayed ultraviolet endonuclease activity and found that all XP fibroblasts have similar activity. Control cells were two lines of normal skin fibroblasts, from subjects aged 3 and 31, a foetal skin fibroblast line, WI-38 foetal lung cells and HeLa cells. Ultraviolet endonuclease activity was assayed by measuring the conversion of ultraviolet-irradiated superhelical PM II phage DNA to the nicked form[6].

PM II phage was grown in host *Pseudomonas* BAL-31 by the method of Espejo and Canelo[11]. PM II DNA labelled with either ^{14}C or ^{3}H-thymidine (New England Nuclear Corp.) was purified by the method of Espejo *et al.*[12], followed by phenol extraction and dialysis against 0.1M NaCl, 0.02 M HEPES-KOH, *p*H 7.5, 0.001 M EDTA. After dialysis, the DNA was dissolved to between 15 and 40 $\mu g\ ml^{-1}$ as determined by 260 nm absorption with specific absorption assumed to be 0.020 $cm^2\ \mu g^{-1}$. Specific activity of the DNA was 2×10^4 d.p.m. μg^{-1}. Ninety per cent of the DNA was in the superhelical form as determined by alkaline sedimentation velocity gradients. Aliquots of DNA were irradiated by a single GE 15-W germicidal bulb (G15T8) from a distance of 15 cm for 2 or 3 min. This irradiation produced 40 or 60 pyrimidine dimers per PM II molecule as determined by the method of Carrier and Setlow[13].

HeLa cells were grown in Joklik modified minimal essential medium supplemented with 10% calf serum. WI-38 cells were obtained through the courtesy of Dr David Sabatini (Department of Cell Biology, New York University Medical Center). Both lines were determined to be free of *Mycoplasma* by culture and uridine phosphorylase assay[14]. *Mycoplasma*-free primary skin fibroblasts and XP skin fibroblasts were obtained from the American Type Culture Collection, Bethesda. Skin fibroblasts and WI-38 were grown on plastic dishes in Dulbecco's modified Eagle's MEM supplemented with 10% foetal calf serum in an atmosphere of 10% CO_2. XP and normal skin fibroblasts grew to 2×10^6 cells per 90-mm dish. Foetal skin fibroblasts and WI-38 cells reached 3×10^6–3.5×10^6 cells per 90 mm dish. WI-38 cells were received and assayed in passage 20–25. Normal and XP skin fibroblasts were received frozen in early passage and assayed within 5–10 subsequent doublings. Cells were prepared for assay by the method of Brent[6] at a concentration of 5–10×10^6 cells per ml. Protein was estimated by the method of Lowry *et al.*[15].

Brent assayed ultraviolet endonuclease of HeLa cells by measuring conversion of irradiated supercoiled PM II DNA to the nicked form by velocity sedimentation through alkaline sucrose gradients since, in neutral sucrose, complexes of the PM II DNA with the HeLa cell preparation prevented resolution of the two forms[6]. Thus, the breaks induced in the DNA could have been hydrolysis of alkali-labile bonds and the enzymatic event assayed a conversion to alkali-labile bonds rather than breaks in the sugar-phosphate backbone[6]. We resolved this problem with neutral caesium chloride gradients. Since caesium chloride had been used in purification of cellular DNA[18] we felt that aggregation of cell protein with PM II DNA would be minimal and the two forms of DNA could be resolved. Caesium chloride velocity sedimentation gradients had been used with polyoma DNA[17].

The gradients in Fig. 1 show that results were identical with alkaline sucrose or neutral caesium chloride gradients. The cell preparation did not attack unirradiated PM II DNA and 2 or 3 min of ultraviolet irradiation did not decrease the percentage of superhelical DNA. The demonstration of nicking of ultraviolet-irradiated superhelical DNA on neutral gradients proves there is ultraviolet endonuclease activity in the cell preparations.

Figure 2 demonstrates comparative activities of the different cell lines. HeLa cell activity increased from 12.5 to 75 µg of protein per reaction mixture. WI-38 activity peaked at similar protein content and was 70% that of HeLa. None of the XP or normal skin fibroblasts had activity greater than 40% that of HeLa, even at protein content as high as 240 µg.

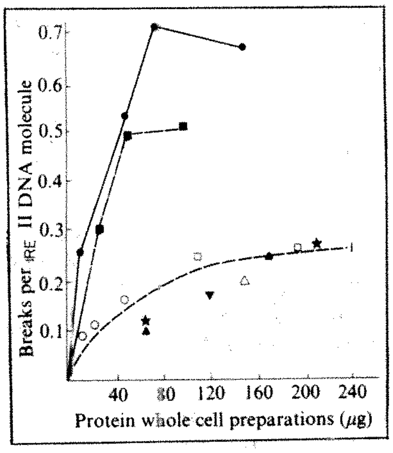

Fig. 2 Comparison of activities of cellular preparations. Conditions of enzyme assay were as described as in Fig. 1 except that the PM II DNA was ultraviolet-irradiated for 3 min. This increased amount of radiation did not in itself cause breaks in the DNA. But it increased the number of breaks introduced by all of the cell preparations. Breaks per PM II molecule were calculated from the Poisson distribution[17] which yields the formula number of breaks $= e^{-x}$ where $x =$ fraction of remaining superhelical molecules. The fractions of superhelical and nicked molecules were determined by summing the radioactivity under each peak. ●, HeLa cells; ■, WI-38; ○, foetal skin fibroblasts (CRL-1106); ▲ and ▼, adult normal skin fibroblasts (CRL-1121 and 1295); ★, △, □ and 1, XP skin fibroblasts from each of the four complementation groups. (CRL-1199, group 4) (CRL-1200, group 1) (CRL-1201, group 3) (CRL-1204, group 2). Each point represents the results of an individual gradient except for HeLa and WI-38 which are the average of two gradients.

These results demonstrate that human cells contain an endonuclease activity that breaks ultraviolet-irradiated circular DNA. This activity is present to a similar degree in XP skin fibroblasts from four complementation groups and three lines of normal skin fibroblasts. Thus, there is no correlation of activity with rates of repair synthesis. This would suggest that this activity is not the ultraviolet repair endonuclease.

The conditions of our assay, however, may not permit estimation of more subtle differences. In *E. coli*, ultraviolet endonuclease activity was the same in crude extracts of wild-type and excision-defective mutants[4]. This paradox was resolved by the demonstration of two UV endonucleases, one of which was absent in *uvrA* and *uvrB* mutants[4]. Therefore, a major endonuclease activity masked that of the true repair endonuclease[4]. Two ultraviolet endonuclease activities have also been identified in *M. luteus*[19].

Our results partially confirm those of Bachetti *et al.* who found no difference in ultraviolet endonuclease activity between one XP fibroblast line and a phenotypically normal XP heterozygote fibroblast[7]. They differ in that our HeLa cell activity was much higher than primary skin fibroblasts. This difference can be explained by the greater sensitivity of an assay using circular rather than linear DNA. This conclusion is supported by the similarity of our results to those of Brent[6].

This increased activity cannot be due to greater DNA content of HeLa cells nor their neoplastic origin since diploid, non-neoplastic WI-38 cells also have high activity. That this is a foetal characteristic shared by neoplastic cells is also unlikely since the primary foetal skin fibroblast activity was the same as adult and XP cells. It is unlikely that this elevated activity is an artefact of cell culture conditions since the foetal skin fibroblasts grew to similar density as did WI-38 and all primary lines were assayed during early passage.

We suggest that several ultraviolet endonucleases are present in human cells as in bacteria and that we measured a composite activity in whole cell preparations. Purification of these endonucleases may explain the relationship of this activity to cellular repair processes.

We thank Mr Archie Cummings for technical assistance. This work was supported by a grant from the US Public Health Service.

Rolling circular DNA associated with Dane particles in hepatitis B virus

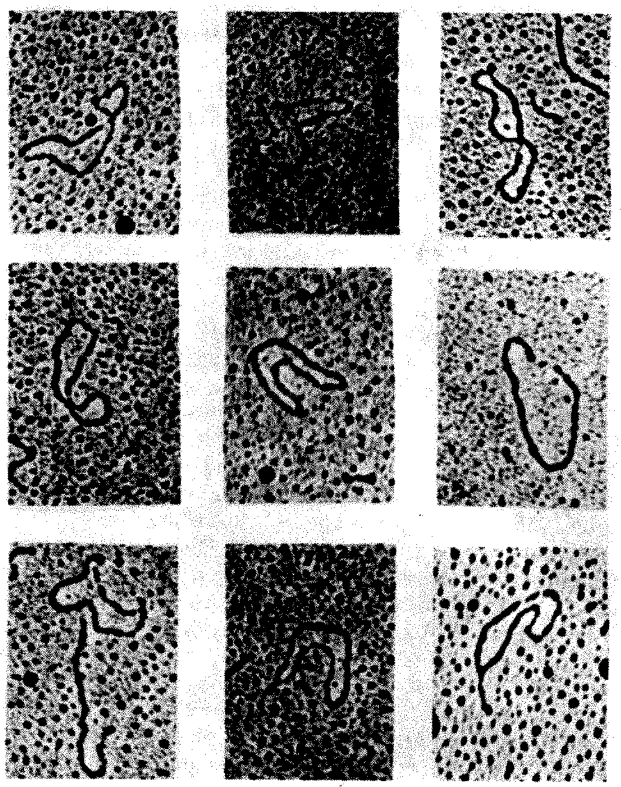

Fig. 1 Circular DNA extracted directly from purified Dane particles (×45,000).

PLASMA of hepatitis B antigen (HB$_s$Ag) carriers consists mostly of spherical particles of diameter 20 nm, together with a much smaller number of filamentous structures with the same diameter. In addition, larger spherical particles, 42 nm in diameter with a 28 nm core, first described by Dane *et al.*[1], are routinely found in crude plasma or purified preparations of HB$_s$Ag. Dane particles also contain a primed DNA polymerase activity[2] capable of synthesising new DNA. Robinson *et al.*[2] examined DNA from Dane particles by electron microscopy and found open, double-stranded circular configurations approximately 0.78 μm long. We have examined DNA isolated from Dane particles directly and also after formation of radioactive products by the endogenous DNA polymerase reaction. The DNA structures appeared in electron micrographs as double-stranded linear strands and closed circles, with examples of completely and partially open circles, and circles with attached linear segments in different lengths. The open circles with attached linear segments are suggestive of a replicative form, and this is consistent with a rolling circle model[4] for replication. This model for replication is strengthened by the comparison of the types of DNA found in particles before and after reaction of the polymerase. The number of rolling circles and the length of the tails were greatly increased after DNA synthesis. This type of replication has not been reported for animal viruses.

Plasmas from commercial blood donors, containing HB$_s$Ag of *ad* or *ay* subtype, were used to isolate and purify Dane particles by density gradient centrifugation and isopycnic banding techniques[2]. DNA polymerase activity and electron microscopy were used to monitor fractions during the isolation and purification. Three Dane particle preparations, shown to be essentially free of 20-nm spherical and filamentous particles be electron microscopy, were purified from approximately 6 l each of HB$_s$Ag-positive plasmas of subtypes *ay* and *ad*. One *ad* subtype and one *ay* subtype particle preparation, containing DNA polymerase activity, were then radiolabelled with ^{3}H-thymidine triphosphate (TTP) for 6 h at 37 °C. The reaction mixture, in a final volume of 12.8 ml, contained 1.6 ml of Dane particle suspension, plus the following reagents at the indicated concentrations: NP-40 detergent, 1%, mercaptoethanol,0. 3%; MgCl$_2$, 40 mM; NH$_4$Cl, 120 mM; Tris-HCl, *p*H 7.5, 160 mM; dATP, dCTP and dGTP, 0.5 mM each; and ^{3}H-TTP (17 Ci mmol^{-1}), 300 μCi.

Radioactive DNA was isolated according to the method of Kaplan *et al.*[2], and although there was insufficient nucleic acid to characterise by absorbancy, the total radiolabelled DNA recovered in the two preparations was 2.2×10^6 d.p.m. for the *ad* plasma and 3.6×10^6 d.p.m. for the *ay* plasma.

The third preparation (*ay* subtype) was divided into two portions. One was incubated for 16 h and extracted as above to yield radiolabelled DNA. The other portion was extracted directly to obtain native particle DNA. The four DNA preparations were submitted to one of us (T.K.) for electron microscopy using the protein monolayer with formamide technique[5].

Double-stranded open circles and linear strands were seen by electron microscopy in DNA extracted directly from purified Dane particles. The circular structures (Fig. 1) were approximately 0.78 μm in contour length, similar to the findings of Robinson *et al.*[3]. The linear structures (not shown) varied in length from 0.5 to 4 μm and there were many simple open circles. Three structures suggestive of tails were observed (Fig. 1, bottom row) in the Dane particle DNA. One of these (bottom right) appears to be an unequivocal rolling circle with a short tail.

The DNA configurations observed by electron microscopy were similar for the three preparations obtained after the polymerase reaction. The linear structures became shorter after incubation, suggesting possible degradation by endogenous nuclease. The most frequently observed structures were the double-stranded open circles and about 20 to 40% of these circular DNA molecules were found as readily identified rolling circles. These structures (Fig. 2) had linear portions with different lengths with an average of 0.55 μm, suggesting various stages of DNA synthesis. Several circles were found with tails longer than unit length. At the junction of the circle and the linear filament, a small single-stranded segment was observed (arrows, Fig. 2). The presence of tailed circles in rudimentary form in native particles, and an abundance of them after a DNA polymerase reaction, suggested that the polymerase-primed DNA in some of the Dane particles replicated by the rolling circle model[4]. This structure is based on one closed circle representing the negative strand to serve as a template for elongation of the positive strand, which grows by the addition of nucleotides to its 3′-hydroxyl end. The model for a double-stranded tail requires that complementary fragments are synthesised on the growing positive strand. The small segments of single strand at the junction of the circle and the linear filament would indicate the site of new synthesis of complementary fragments.

Although the infectious form of hepatitis B virus has not been identified, the Dane particle is a leading candidate for the infectious agent. The findings that a unique closed circular DNA and a DNA polymerase are associated with purified Dane particles are consistent with the hypothesis that a Dane particle containing nucleic acid is an infectious virion. The molecular weight of the circular DNA calculated from the mean contour length of 0.78 μm was about 1.6×10^6. This is similar to the findings of Robinson *et al.*[3] and indicates that the DNA is smaller than the double-stranded DNA of any known virus. The genetic information carried by DNA of this size is therefore very limited, and if this DNA represents the viral genome, some unique additional system, such as complementation or helper virus, may be required to programme the life cycle of the virus. Further studies will be necessary to establish whether the native configuration of the DNA is a superhelix or a 'nicked' open circle. Structures suggestive of superhelices (not shown) were observed, but could not be demonstrated reproducibly in these studies. The presence of an active, primed DNA polymerase in the native particles from plasma suggests the possibility of initiation of DNA synthesis in some Dane particles in blood or plasma. Although they were infrequent, short tails were observed in circular structures obtained directly from the particles before the *in vitro* incubation for DNA synthesis, indicating that initiation of replication by rolling circles had already taken place in a few particles. The quantity of rolling circles and the length of the tails increased significantly after incorporation of nucleotides. Thus, the *in vitro* polymerase reaction could result in elongation of pre-existing tailed circles as well as in new initiation of replication by rolling circles. The *in vitro* reaction is a highly artificial incubation condition, and therefore the rolling circles reported here may or may not represent the actual mechanism *in vivo*. Confirmation of the rolling circle mechanism of replication should be of interest because it would represent the first example known to us of this mechanism of replication of DNA obtained from a mammalian virus system.

Chemical and immunological differences between normal and tumoral colonic mucoprotein antigen

WE have found immunological and chemical differences between the colonic mucoprotein antigen (CMA) isolated from normal and tumour tissue. CMA is one of at least ten antigens reported from human colonic mucosa, one or more of which has been claimed to be tissue specific. Nairn[1] demonstrated histologically that one of these was a mucoprotein similar to the blood group substances, yet distinct and specific for the gastrointestinal system. Its clinical importance was emphasised by Bromberger and Perlmann[2], who demonstrated the presence of antibodies to it in the sera of patients with ulcerative colities. The differences reported here may be useful as diagnostic markers for colonic carcinoma.

The colonic mucoprotein antigen (CMA) accounts for

1% of the wet tissue weight and is chemically similar to the blood group substances but not antigenically related to them. CMA is also clearly distinct from the carcinoembryonic antigen (CEA) system. There is no major variation in the nature of the molecule between normal individuals although there is some microheterogeneity because of the size (1.5×10^7 daltons).

Tissues obtained either from surgery or at autopsy and stored at −70 °C until use were two primary adenocarcinomas (T1 and T2) and one metastasis from the liver (T3) from different patients. The tumour mucoprotein was purified as described previously for CMA[3]. Briefly, a phenol–water extraction was performed, the water layer was concentrated and fractional ethanol precipitation was carried out. The precipitate was subjected to gel chromatography on Sepharose 2B or 4B, the excluded peak being the product.

Elution profiles of the primary carcinomas on Sepharose 4B were identical to that of the normal tissue. There was an excluded peak at 28% bed volume containing the mucoprotein and an included peak at about 80% bed volume containing albumin, low molecular weight RNA and yellowish *E. coli* antigens[4]. The liver metastasis extract had a similar profile, without the *E. coli* antigens. The product yield of these tumours on a percentage of wet weight basis varied from one-third to one-half that of the normal tissue.

Antisera were prepared in rabbits, using purified material isolated from pooled normal colonic mucosa and the two primary tumours. A human red cell typing panel and antisera were obtained from Schering Diagnostics. Goat anti-CEA antisera (G100) was given by Dr J. Fierer of Francis Delafield Hospital, New York. Double diffusion studies were performed by the method of Ouchterlony[5].

Figure 1*a* shows the double diffusion reactions between antiserum prepared against normal colonic mucoprotein (centre well) and the normal and tumour-derived mucoproteins (peripheral wells). A single line is seen in each case. The tumour mucoproteins have reactions of partial identity both with respect to each other and with respect to the normal CMA. With this antisera it can be seen that the tumour mucoproteins do not all contain the same antigenic determinants and that the normal CMA contains determinants not present in either of the tumour products.

Anti-T1 antisera gave a reaction of identity with the three tumour mucoproteins (Fig. 1*b*), but no reaction with normal CMA. Anti-T2 antisera gave the same pattern (Fig. 1*c*), except for a spur on the T2 line indicating the existence of determinants present in T2 but not in T1. Again there was no reaction with normal CMA. This demonstrated an antigenic determinant (or conformation) specific for the tumour mucoprotein. None of the purified materials reacted with any of the blood typing antisera, nor did any of the prepared antisera agglutinate red cells from the typing panel. Goat anti-CEA antisera did not react with any of the purified materials.

Table 1 Amino acid composition and molar ratios

	CMA	T1	T2	T3
Thr*	17.4	4.0	5.9	2.6
Pro*	6.7	3.1	3.9	2.0
Val*	4.0	2.0	1.8	1.2
Ile*	2.3	1.1	1.2	0.7
Glu	5.0	4.9	5.0	3.3
Gly	3.9	4.2	3.9	3.1
Asp	3.7	3.6	3.4	3.7
Ser	3.7	3.5	3.8	3.1
Leu	3.3	3.2	3.0	2.5
Ala	3.1	3.0	3.1	2.3
Lys	2.3	2.4	2.9	1.8
Arg	1.8	1.2	1.3	1.1
His	1.4	0.9	0.9	0.7
Phe	1.3	1.3	1.4	1.1
Met	1.0	0.3	tr	—
Tyr	1.0	1.0	1.0	1.0

Samples were hydrolysed at 110 °C with 2.5 N HCl for 4 and 20 h and analysed with a Beckman Model 121 analyser. Cysteine and tryptophan were not determined.

*These represent significant differences between the examined mucoproteins.

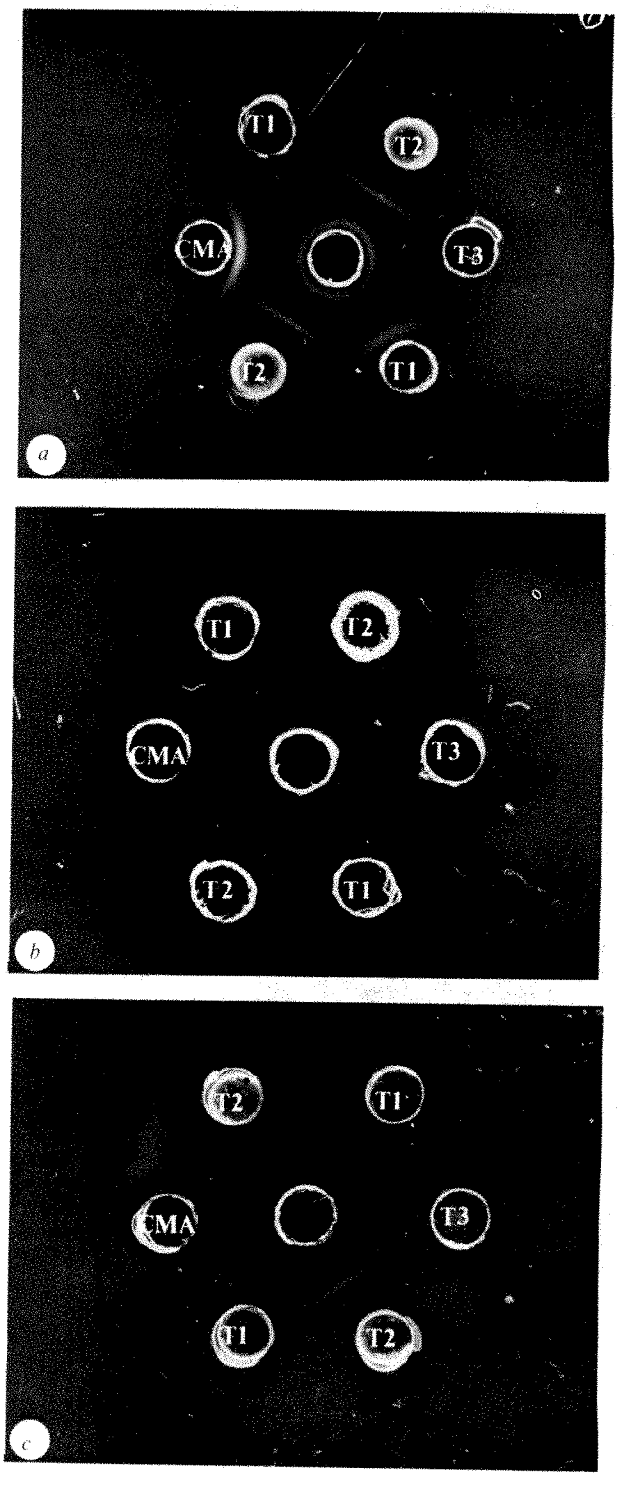

Fig. 1 Double diffusion analysis. Antisera in centre wells were: *a*, anti-CMA; *b*, anti-T1; *c*, anti-T2. Peripheral wells contained the purified mucoprotein from normal tissue (CMA) and the three tumours T1, T2 and T3.

Thus there is a clear distinction between CMA of normal and tumour origin. It must be stated initially that CMA is not made up of subunits. If this were the case, it might be argued that the tumour product could be a subunit analagous to the Bence-Jones proteins in multiple myeloma. Gel chromatography of normal CMA with phosphate-buffered saline, high salt or 6 M urea gave identical elution profiles. Reduction and alkylation in the presence and abscence of 6 M guanidine revealed no interchain cystine bridges The reduced and alkylated material eluted with the unreduced material when cochromatographed. More extensive analysis for subunit structure was performed on the equivalent material isolated from rat colon[6] No subunit structure was detected.

Amino acids were analysed using a Beckman Model 121 analyser after hydrolysis with 2.5 N HCl under a nitrogen atmosphere at 110 °C for 4 and 20 h. Extrapolated molar ratios (Table 1) were significantly similar for the four materials but there was less threonine, proline, valine and isoleucine in the tumour mucoproteins. The protein-carbohydrate linkage is O-glycosidic between galactosamine and threonine, possibly with a small percentage of prosthetic groups attached to serine in CMA. In many glycoproteins with this type of linkage, proline and isoleucine are found in close association with the site of linkage. Therefore it seems that the tumour cells synthesise at least some molecules similar in amino acid composition to those of the normal cell except that the linkage sites are absent.

Carbohydrate content was determined by gas chromatography of the alditol acetates[7]. Neuraminic acid analysis was performed after treatment with neuraminidase, by the thiobarbituric acid assay[8]. Paper chromatography[9] showed that the neuraminic acid exists as the N-glycolyl derivative The concentrations of the individual sugars varied from one tumour to the next, as Table 2 shows. T1 and T2 contained less carbohydrate than CMA, while T3 contained more. The molar ratios of T1 and CMA were similar while the other tumours showed greater divergence.

Table 2 Component analysis

	CMA (g per 100 g)	Molar ratio	T1 (g per 100 g)	Molar ratio	T2 (g per 100 g)	Molar ratio	T3 (g per 100 g)	Molar ratio
Fucose	7.03	7	3.92	5	0.83	1	15.99	15
Galactose	13.09	12	5 33	6	4.06	5	21.95	18
Glucosamine	11.36	10	8.63	10	7.88	10	11.91	10
Galactosamine	10.92	10	7.81	9	10.06	13	3.33	2
N-glycolyl-neuraminic acid	15.37	8	4.63	3	14.63	10	3.51	2
Protein	32.58		61.93		48.96		28.62	

Sugars were analysed by gas chromatography of the alditol acetates after hydrolysis in 1.0 N HCl for 1 h at 100 °C and 2.0 N HCl for 2 h at 100 °C. N-glycolyl neuraminic acid was determined by the thiobarbituric acid assay, protein using the amino acid analyser.

A larger group of tumours is being analysed to define this heterogeneity more exactly and perhaps relate it to antigenic differences. It may be analogous to that found in myeloma proteins, where there is a large degree of both central and peripheral heterogeneity in the carbohydrate prosthetic groups. Our results show that there is a distinction between the normal and tumour mucoproteins which may be useful in the detection of colonic carcinoma.

Difference between the two iron-binding sites of transferrin

THE protein transferrin has a central role in iron metabolism, transporting the metal between absorption, utilisation, excretion, reclamation and storage areas. Although two ferric ions are bound at apparently equivalent iron-binding sites[1], the sites behave in a non-equivalent manner. Since the initial report by Fletcher and Huehns[2], there have been observations *in vivo* and *in vitro* of the unique biological specificity for transferrin iron bound at each site[3–8]. Physicochemical evidence for any difference between iron binding at each site is sparse. Price and Gibson[9] observed electron paramagnetic resonance (EPR) spectral differences arising from each site under the influence of the chaotropic agent perchlorate. Aisen *et al.*[10] observed EPR differences between sites for the chromium complex and Young and Perkins[11] reported that bicarbonate displaces only one oxalate anion from the (oxalate)$_2$–Fe$_2$–transferrin complex. We now report experiments on the *p*H-dependent dissociation of diferric transferrin which indicate that there is a difference in the iron-binding properties of each site.

Human transferrin (Beringwerke) was dissolved in water (250 mg per 25 ml) and dialysed[12]. The final dialysate was a solution of 0.010 M N-2-hydroxy-ethylpiperazine-N′-2 ethanesulphonate-0.001 M NaHCO$_3$, *p*H 7.45. Transferrin complexes were formed by mixing the apotransferrin solution with increasing amounts of 1.00×10^{-4} M tracer ^{59}Fe-labelled ferric dinitrilotriacetate, *p*H 6.0 (FeNTA$_2$). After incubation at 37 °C for 30 min, each solution was passed through a small buffer-equilibrated column (0.6×4 cm) of anion exchange resin (Biorad AG 1×4, Cl$^-$ form), and counted in a well-type gamma detector. Protein-bound iron was completely eluted from the resin, while iron in excess of the binding capacity was retained by the resin. The ^{59}Fe activity of eluates saturated with iron was used to determine the binding capacity and the transferrin concentration.

Four diferric transferrin solutions were prepared. Sample *A* was labelled with ^{59}Fe at *p*H 7.45. Samples *B* and *C* were mixed with ^{59}Fe (*B*) or unlabelled iron (*C*) at *p*H 5. *D* was not treated with iron at *p*H 5.00, *B* and *C* after removal of unbound iron were fully saturated with unlabelled and labelled iron respectively at *p*H 7.45 and *D* was saturated with ^{59}Fe at *p*H 7.45. Iron dissociated from these preparations as a function of *p*H was measured by resin absorption of dissociated iron.

Triplicate samples of apotransferrin were treated as follows. To sample *A*, at *p*H 7.45, was added 10% excess of ^{59}Fe–FeFeNTA$_2$. To sample *B*, adjusted to *p*H 5.00 with 0.01 N HCl, a 10% excess of ^{59}Fe–FeNTA$_2$ was added. To sample *C*, at *p*H 5.00, a 10% excess of unlabelled FeNTA$_2$ was added. Nothing was added to sample *D*, at *p*H 5.00. Each set of tubes was incubated and passed through resin columns which had been washed with HEPES medium at the corresponding *p*H. After determination of ^{59}Fe activity in samples *A* and *B*, 1 ml of 0.04 M HEPES–0.01 M NaHCO$_3$ solution (*p*H 7.45) was added to each eluate (3 ml), bringing the *p*H 5.00 eluates to *p*H 7.45. A calculated 10% excess of ^{59}Fe–FeNTA$_2$ was added to samples *C* and *D* to saturate the protein. Sample *B* was resaturated with a 10% excess of unlabelled FeNTA$_2$. The solutions were reincubated, passed through resin columns at *p*H 7.45, diluted to 10 ml (final transferrin concentration of 0.005 mM) and counted.

Sample *D* contained 97% of the activity of sample *A*, indicating that there was no loss of apotransferrin nor any alteration of binding capacity of the transferrin during these procedures. Sample *B*, initially labelled at *p*H 5.00 with ^{59}Fe and resaturated with unlabelled iron at *p*H 7.45, contained 41% of the activity of fully labelled transferrin (*A*). Sample *C*, labelled in the reverse manner, contained 62% of the activity present in *A*.

Samples of 1 ml from each of these solutions (*A*–*D*) were delivered into 0.5 ml of 0.10 M Tris-maleate buffers, *p*H 4.8–6.4. After standing for 45 min at room temperature, the contents of each tube were transferred to resin columns equilibrated with 0.01 M buffer at the corresponding *p*H. Tubes and columns were rinsed with three 0.5-ml samples of 0.01 M buffer, the eluates were counted, and the percentage of the total radioactivity was calculated. In these conditions, less than 0.5% of ^{59}Fe activity added to the buffers as $FeNTA_2$ or $FeCl_3$ was eluted from the resin.

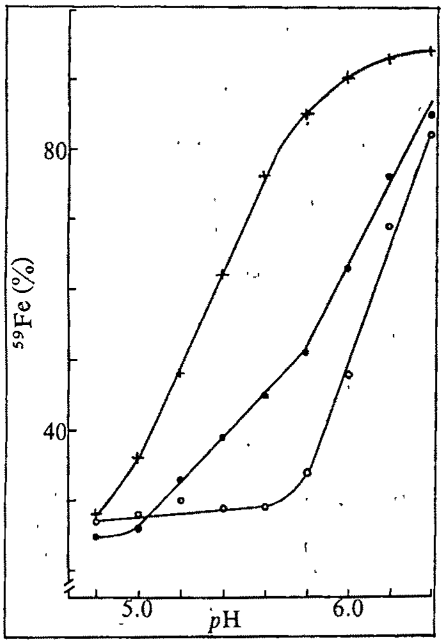

Fig. 1 Transferrin iron-binding in the *p*H range 4.8–6.4 Sample *A* or *D* (●) uniformly labelled ^{59}Fe diferric transferrin. Sample B (+) initially labelled with ^{59}Fe at *p*H 5, saturated with unlabelled Fe at *p*H 7.45. Sample *C* (○), initially labelled with Fe at *p*H 5, saturated with ^{59}Fe at *p*H 7.45.

Figure 1 shows that the percentage of ^{59}Fe bound to transferrin in the eluates from sample *A* or *D* (fully labelled with ^{59}Fe) as a function of the *p*H comprised two linear components intersecting near *p*H 5.8 where half of the metal was still bound to the protein. The ^{59}Fe-iron in sample *B*, which was initially labelled with ^{59}Fe at *p*H 5 (41% ^{59}Fe) and subsequently saturated with unlabelled iron at *p*H 7.45, was more stable to dissociation at corresponding *p*H than the fully labelled preparations (*A* and *D*). The dissociation was linear at *p*H 4.8–5.8. Sample *C*, which was resaturated with ^{59}Fe, also exhibited a simple linear relationship between the transferrin-bound ^{59}Fe but at *p*H range 5.8–6.4. This ^{59}Fe-labelled ferric ion occupied the site which did not bind iron at *p*H 5.00 and dissociated more readily at corresponding *p*H than the other samples when the *p*H was reduced below 5.7, 25–30% of the ^{59}Fe remained bound (*A*, *B* or *D*).

The biphasic nature of the *p*H-dependent dissociation observed with diferric ^{59}Fe-labelled transferrin suggests that there is a difference in the binding properties of each site at low *p*H which has not been reported before. Apparently one transferrin iron-binding site can bind a ferric ion at a lower *p*H than does the other site. Thus at *p*H 5, sample *B* bound the ^{59}Fe (approximately 0.8 mol of Fe per mol of transferrin) and sample *C* bound the unlabelled isotope. When the *p*H was adjusted to 7.45 and each sample was then resaturated with alternate isotope, 83% (1.0 of 1.2 additional iron) would occupy the second site. The dissociation data indicate that at *p*H 5.7 the uniformly labelled transferrin sample (*A* or *D*) still bound one ferric ion (50% of the ^{59}Fe). At this *p*H 32% (0.38 ^{59}Fe) of sample *C* and 85% (0.67 ^{59}Fe) of sample *B* was bound to the protein. The ^{59}Fe of *C* that was undissociated from *p*H 4.8–5.7 reflects that a portion of the ^{59}Fe occupies the more acid stable site. The metal binding characteristics are sigmoidal at high *p*H and when the *p*H is below 5.0.

If each site had equivalent iron-binding properties, when the complex was formed at *p*H 5, the ferric ions would distribute randomly between each site, and on resaturation at *p*H 7.45, the second isotope would also be distributed equally between both sites. Subsequent dissociation at low *p*H should not favour either site or isotope. The dissociation of ^{59}Fe in sample *B* or sample *C* should then be identical. This is not supported by Fig. 1.

The difference in iron-binding at *p*H 5 may arise with a conformational change to the protein such that one site becomes altered or even masked from iron-binding at low *p*H. When the protein reverted to its normal conformation at neutral *p*H, additional ferric ion would be bound at this unique, empty site. Although we have no information of such a conformational change, this mechanism could explain our finding.

There was a difference in the amount of iron bound by apotransferrin at *p*H (41% of the level at *p*H 7.45) and the amount dissociated from diferric transferrin in Tris-maleate buffer at *p*H 5 (26% of the level at *p*H 7.45) so that the data may not represent true equilibrium binding. However, the dissociation data agree with previous findings[13]. In studying the effect of *p*H on absorbance at 465 nm with ferrous ammonium sulphate and transferrin maintained overnight at 5 °C in the absence of buffers, Sturgenor *et al.* found that binding was complete when the *p*H was above 6.5 and was 50% of this value near *p*H 5.6, which is close to the value we observed (5.7) for 50% dissociation. The discrepancy between the association and dissociation binding values may be the result of differences in the ionic strength in each study, or may involve the participation of maleate in some manner. This, however, would have little bearing on our comparative dissociation study since all samples were treated similarly.

That one ferric ion, which is presumably bound at one specific iron-binding site, is dissociated more readily than is the other ferric ion could account for the biological utilisation of iron selectively from one binding site.

This investigation was supported in part by grants from the National Institute of Arthritis, Metabolism and Digestive Diseases and the Washington Heart Association.

Imagery used to change behaviour

Ronald C. Lyle

Imagery and Daydream Methods in Psychotherapy and Behaviour Modification. By Jerome L. Singer. Pp. xi+273. (Academic: London and New York, 1974.) $16.50; £7.90.

THIS book attempts to straddle the chasm alleged to separate psychotherapeutic and behavioural approaches to the treatment of the 'mentally ill'. In a brave attempt to integrate widely differing approaches, Singer has sacrificed depth for breadth of coverage, and the overall impression is of a somewhat variable series of chapters rather than of an integrated whole.

The first chapter is, to a degree, bewildering; but by the second, I had begun to appreciate the literary style, despite some superficiality of content. Mention of philosophy is curiously confined to late 19th century North American philosophers/psychologists, and there is no consideration of the mind/body problem, nor even an account of the cognitive/behaviourist controversy within psychology. An interesting summary of the imagery methods currently used in psychotherapy is, however, included although it gives the impression of being a rather cursory overview.

The chapters on behaviour modification similarly lack a sufficiently detailed exposition of the underlying theories which Singer is seeking to replace with his own. Singer hits at the counterconditioning theory of desensitisation, but ignores the fact that most behaviourists have already moved to an habituation model. He mentions cursorily the use of deliberate exposure to real life situations, whether using low-intensity stimuli in the case of desensitisation, or prolonged exposure to highly anxiety-provoking situations in the case of flooding. Both of these procedures are now favoured in view of the difficulties which have been encountered with attempts to transfer to real life situations treatment carried out using imagined scenes. Although there are several techniques for using punishment to reshape behaviour, commonly based on electric shock, Singer devotes disproportionate space to the work of Cautela, who uses an imagined scene as the aversive stimulus. He also misses an opportunity to cite McGuire's work on the acquisition of deviant sexual behaviour by masturbation to fantasy imagery.

Singer follows this with a brief outline of experimental work on imagery, which relies heavily on self-report. Perhaps some mention of personal construct theory would have been relevant in this context. He then briefly outlines a theory relating affect and assimilability of information which seems to bear similarities to Pribram's better articulated concept of emotion as the degree of match/mismatch between stimulus input and expectancies.

A general theory of imagery is advanced which would allow the incorporation of psychodynamic concepts, in as much as early childhood experiences may provide generic categories for later information storage. In the final chapter, Singer rather hastily and unconvincingly discards conventional theories of specific procedures of behaviour modification for vague explanations in terms of cognitive restructuring.

I would not recommend this book as a comprehensive view of the imagery methods used in behaviour modification, although the summary of imagery methods used in psychotherapy is interesting. The book would have been more successful had it been more restricted in scope. ☐

Working in the cold

G. R. Pickett

Experimental Principles and Methods Below 1 K. By O. V. Lounasmaa. Pp. xii+316. (Academic: London and New York, September 1974.) £7.80; $20.25.

THE recent discovery of the existence of two superfluid phases of liquid ^{3}He below 2.6 mK has refocused attention on very low temperature physics. The field is at something of a critical point at present. The lowest attainable temperatures, which have been hovering around the 1–2 mK mark for more than a decade, seem about to advance into the microKelvin region, with all its interest of nuclear ferromagnetism, as nuclear cooling now seems to be less difficult than previously thought. It is thus a timely point for the appearance of a textbook on current experimental techniques below 1 K.

Lounasmaa's stated intention has been to write a book treating the four cardinal problems of low temperature physics: how to cool to low temperatures, how to measure the temperature when there, how to establish thermal contact and how to maintain thermal isolation The book keeps very close to this intent. The reader is led gently into the field with a discussion of the ^{3}He refrigerator before being introduced to the serious subject matter of the book which—in spite of the title—is experimental principles and methods below 100 mK The author has a clear expository style and deals with his subject in a straightforward manner. The chapter on dilution refrigerators perhaps makes these devices seem simpler than they are and a fuller discussion of some of the problems would have been helpful. Very little actual experimental work is discussed beyond that which touches directly on the problems of cooling, thermometry and thermal contact or isolation; and this restriction has limited the book to a manageable size. The one exception, which the author could not resist putting in, is the chapter on the superconducting quantum interference device, or SQUID, which, although not specifically a very low temperature device, is certainly useful in this regime.

The book is also a valuable source of reference. The chapter on thermal contact and isolation has a number of useful compilations of thermal conductivities and Kapitza resistances of commonly used materials. There is a very comprehensive author and subject index and an appendix of suppliers of low temperature instruments, equipment and materials, although this is likely to become rapidly out of date. Rigorous SI units are used throughout; pity is, however, taken on weaker brethren by the inclusion of conversion tables of SI to other units. A valuable book for any low temperature group to have access to and at the price not too expensive for the new graduate student to aspire to his own copy.

Directed illumination

Laser Physics. By Murray Sargent III, Marian O. Scully and Willis E. Lamb, Jr. Pp. xxvii+432. (Addison-Wesley: Reading, Massachusetts, and London, November 1974.) $13.50 paper; $22.00 cloth.

To an experimental physicist, some theoretical papers are memorable because they unify masses of phenomena into a theoretical structure and at the same time point the way to future developments. Such a paper was Willis Lamb's *Theory of an Optical Maser* published in the *Physical Review* in 1964. On one side, a satisfying structure was set up for analysing frequencies and intensities in multi-mode lasers. On the other, mode locking and interaction phenomena were suggested, and it could well be argued that the paper provided an impetus for the heated debate between 'classicists' and 'modernists', which has raged in quantum optics over the last few years.

This new text by Lamb and his co-workers was, therefore, awaited with much anticipation, and has lived up to that anticipation. It has succeeded in doing something which many texts fail to do: taking students in a pedagogical framework from undergraduate quantum mechanics and optics to the present boundaries of the subject.

A discussion of atom–field interactions in terms of perturbation theory sets the scene and is followed by chapters on oscillators and on the maser. Density matrix formulation is discussed and is followed by the semi-classical laser theory, which was the subject of Lamb's 1964 paper, expanded and reorganised. Specific examples of the applications of the theory, such as gas lasers, are then treated. A chapter on the quantum theory of radiation leads into the quantum theory of the laser field and its fluctuations. Finally, appendices are provided to tidy away topics such as the modes of passive cavities and plasma dispersion functions which would break the flow of the main text. Examples and problems are provided at the end of each chapter and these are usually illuminating and often highly suggestive to the experimentalist. Sensibly, given the mass of laser literature, few primary sources are quoted, but the reader is referred to secondary sources for all necessary information.

It is fair to say that as a text book of laser theory it is unlikely to be surpassed. As the authors suggest, it could easily form the basis of a whole third year undergraduate quantum mechanics course, although there might be objections from nuclear and solid state lobbies. There are few textbooks which the average physics researcher can read through purely for pleasure, but this excellently produced and clearly laid out text may well become one of them.

D. G. C. Jones

Laser Light Scattering. By Benjamin Chu. Pp. xii+317. (Academic: New York and London, September 1974.) $31.50; £15.10.

A POWERFUL method of investigating the structure of non-crystalline substances is based on the study of the angular distribution of the intensity of scattered radiation. The history of this study dates back to Tyndall's experiments of 1869 and we may, of course, refer to the classical investigation of Lord Rayleigh on the blue light of the sky. The radiation used in scattering studies may be visible light (which is scattered without being absorbed by gases, liquids and suspensions or solutions of solid particles), X-rays or neutrons. We owe to Einstein and to Debye, in particular, credit for the theoretical apparatus which made it possible to determine the absolute molecular weight, thermodynamic interactions, and the size and shape of a variety of natural and synthetic particles or macromolecules of biological interest.

The advent of the laser has stimulated greatly the study of the spectral features of scattered light and the information concerning molecular structure which can be derived from this analysis; Brillouin first predicted in 1914 that such features would arise in liquids thermally excited by sound waves. By shifting the analysis from optical into radio frequency fields, light beating spectroscopy has allowed us to attain resolutions orders of magnitude greater than those accessible to classical spectroscopic techniques. The digital photoelectron autocorrelation technique has transferred the analysis from the frequency domain into the time domain, to which it is related by a simple transform. Spectral widths ranging from 1 to 10^8 Hz are now easily accessible through a number of relatively simple techniques (Raman scattering, which has also benefited greatly by the introduction of laser sources involves higher energy shifts). Developments within the last decade have shown that particle motions as diverse as the diffusion of molecules in Brownian motion, the chemotactic response of motile bacteria, the internal motion of flexible macromolecules or structures, or the velocity of wind, can all be analysed in terms of the spectral broadening in the frequency domain or the photoelectron autocorrelation properties of the scattered light.

Laser Light Scattering is timely because it attempts to present, in one useful integration, the various aspects, both theoretical and experimental, of this exciting new technique. I am not aware of a comparable source of information encompassing both practical and theoretical aspects of the problem in this rapidly expanding field. Yet the results of this heroic attempt have been only partially successful; too much has maybe been attempted in a book of a relatively modest size. The chemist and the biologist may remain somewhat bewildered by the fragmentary derivations whereas the physicist may expect a more advanced level of presentation.

Chu is, however, aware of that difficulty and provides enough references for additional detailed information. He discusses the intensity and the spectrum of the scattered light, the coherence properties and photoelectric detection of the scattered electric field, optical mixing spectrometers, Fabry–Perot interferometers and theoretical and practical aspects of photocount autocorrelation, lasers, optical systems, photomultipliers and data analysis. Finally, he reviews applications of the study of macromolecules, reaction kinetics, concentration correlation spectroscopy (with fluorescent probes), anemometry and critical opalescence. The book may indeed serve as a useful introduction to the interdisciplinary area of laser light scattering.

Henryk Eisenberg

Drug generalisations

Drug Actions on Cholinergic Systems. (Pharmacology Monographs.) By R. W. Brimblecombe. Pp. 227. (Macmillan: London and Basingstoke, January 1975.) £9.95.

THE first third of this book is devoted to a discussion of the action of acetylcholine like substances and their antagonists on peripheral receptors. Although it would be fatuous to deny that there must be some relationship between the chemical structures of such drugs and their pharmacological activity, it remains a secret relationship and structure-activity data have not provided the insights, perhaps over-optimistically hoped for 20 or so years ago. Some important advances, it is true, have been made, but these have been mainly in relation to the variation in the actions of different members of homologous series: at present it seems altogether too much to hope that the structures of receptors can be deduced from those of known agonists and antagonists. Unfortunately, however, it is precisely the not very convincing attempts to do just this, that the author has chosen to stress in his introductory chapters. One particular difficulty, of which the reader is not made sufficiently aware, is that in so far as agonists are concerned, biological activity is only partly related to affinity. The situation is in principle simpler with antagonists, but in practice the diversity of effective structures is discouraging.

The greater part of the book is devoted to a survey of effects which have been attributed to the actions of drugs on acetylcholine receptors in the central nervous system. Here too, I wonder if the selected literature, much of it concerned with behavioural changes which are not too well established is really worth summarising in book form. Perhaps statements like (p. 202) "... considered that it was not inconsistent with the hypothesis that nicotine stimulates the brain-stem activating system to produce behavioural arousal" cause arousal in some minds, but they are not likely to convey much to readers with a more general interest in cholinergic systems.

It is also difficult to accept that there is evidence to justify, even as a simple working hypothesis, the idea that all acetylcholine receptors in the central nervous system may be categorised as muscarinic or nicotinic, or that drug actions on behaviour may be described simply as stimulant or depressant (or of course biphasic); or (p. 194) that "nicotinic action is primarily on the brain stem and hippocampus while the muscarinic action is directly on cortical neurones".

The author is certainly well aware of the confusions and the controversies and the uncertainties of the present state of affairs. This does not, however, deter him from making rather large generalisations of the kind that are useful in elementary text-books. This seems to be a question of policy, since an extract from his general conclusions (p. 215) reads "... it would be premature at the present state of knowledge to attempt to explain the role of central cholinergic systems in anything more than the most general terms". Evidently the author does not agree that in pharmacology the particular must precede the general.

B. L. Ginsborg

Polypeptides

The Chemistry of Polypeptides. Edited by P. G. Katsoyannis. Pp. xiii+417. (Plenum: New York and London, 1973.) $34.20.

THIS book is a collection of essays on different aspects of peptide chemistry, written by eminent scientists in honour of Leonidas Zervas. Appropriately, the opening chapter by P. G. Katsoyannis describes the life and scientific work of Leonidas Zervas, from his being awarded the degree of PhD in Chemistry at the University of Berlin, to his retirement from the Chair of Organic Chemistry at the University of Athens in 1968.

Zervas's most remembered contribution to peptide chemistry is the use of carbobenzoxy protecting groups in peptide synthesis and this epoch-making discovery is stressed in the opening paragraphs of several chapters.

J. Rudinger, in discussing the relative merits of the even older tosyl protecting group (originally described by Emil Fischer in 1915), emphasises that peptide chemists should perfect the use of each available protecting group rather than abandoning it when an apparently better one comes along. Hirschmann and Veber contribute an interesting chapter on the concept and advantages of minimal protection in peptide synthesis, including the thiol group of cysteine Bricas appropriately describes, in view of Zervas's pioneering work on the synthesis of a glycopeptide, the present state of knowledge on the structure and synthesis of peptidoglycans and an unusual and interesting inclusion in a book of this kind is written by H. Hanson, on the mechanisms of intracellular proteolysis.

This book provides an historical review of assorted aspects of peptide chemistry with an extensive bibliography, but is not designed as laboratory text.

announcements

Award

Sören Jensen has been awarded the **Grand Prix** of the Swedish Royal Academy of Sciences for the identification of a polychlorinated biphenyl potentially dangerous to the environment.

Appointments

The University of Adelaide has appointed **Professor K. A. Provins** of the Department of Psychology in the Australian National University to the second of two Deputy Vice-chancellor positions. **Professor E. S. Barnes**, of the University's Department of Pure Mathematics, took up the other post at the beginning of this year.

Miscellaneous

Cancer study grants. The International Union Against Cancer is supporting the Yamagiwa–Yoshida Memorial Grants, designed to enable investigators to gain experience in special techniques in both the biological and clinical aspects of cancer research. Available only for study outside grantee's country of residence, as intended to encourage international collaboration (PO Box 400, 1211 Geneva 2, Switzerland).

International meetings

May 26–28, **World energy conference,** Copenhagen (DIS Congress Service, 36 Skindergarde, DK-1159 Copenhagen K, Denmark).

May 26–30, **Hot atom chemistry,** Louvain-la-Neuve (Professor Diapers, Laboratoire de Chimie Inorganique et Nucleaire, Chemin de Cyclotron 2, 1348 Louvain-la-Neuve, Belgium).

May 29–31, **Oncology and experimental models in cancer immunotherapy,** Bucharest. (Secretariat, Congress of Oncology, Boulevard 1 May 11, Sec 8, POB 5916, Bucharest 12, Rumania).

June 1–7, **Rheumatology,** Helsinki (European Rheumatology Congress, Box 30 00101 Helsinki 10, Finland).

June 2–5, **Smoking and health,** New York (Mr H. Milt, Staff Co-ordinator, 3rd World Conference on Smoking and Health, American Cancer Society, 219 East 42nd Street, New York).

June 23–July 4, **Radiation protection,** London (Dr H. D. Evans, Department of Chemical Engineering and Chemical Technology, Imperial College, London SW7, UK).

June 24–July 3, **Chemistry of solid–liquid interfaces,** Cavtat-Dubrovnik, Yugoslavia (IV Summer Chemistry Conference, Dr Velimir Pravdic, Rudjer Boskovic Institute, POB 1016, YU-41001 Zagreb, Yugoslavia).

June 30–July 4, **Entomology,** London (The Director, Commonwealth Institute of Entomology, 56 Queen's Gate, London SWY 5JR, UK).

July, **Pathological physiology,** Prague (Dr F. Palecek, Scientific Secretary of the Congress, Ke Karlovu 2, 121 09 Praha 2, Czechoslovakia).

July 2, **Mathematics of biological rhythms,** Cambridge (Secretary and Registrar, The Institute of Mathematics and its Applications, Maitland House, Warrior Square, Southend-on-sea, Essex, SS1 2JY, UK).

Person to Person

Exchange of hospitality. Two sons and one daughter of Professor M. Sandler, aged twelve, eleven and ten respectively, separately seek hospitality in French household for two weeks this summer in exchange for return visits. All have some knowledge of the language (Queen Charlotte's Hospital, Goldhawk Rd, London W6 0X6, UK).

Leaf colour changes. Biologist visiting Canada during September/October this year would be interested to know whether any of the complex pathways for the production of compounds causing the myriad colours of leaves during the Canadian fall, have been elucidated in detail (Mr R Wylie, Loudoun Cottage, Whitchurch Road, Spurstow, Tarporley, Cheshire, UK).

For those in peril on the sea

H. Russell Bernard, an associate professor of anthropology at West Virginia University, has spent six weeks aboard American research vessels under the sponsorship of the Office of Naval Research (ONR) studying the relations between crew and scientists. At the end of it he declares that "when they are not working together, they are working at staying out of each other's way. Physical isolation of crew and scientists was achieved by an elaborate time and space-sharing scheme . . . [which] may be seen as a manifestation of a gulf in values and behaviour in general". I wish the ONR had asked me; for half the price of placing an anthropologist on a ship I would have been happy to tell them that in the average research ship there are large spaces, even whole decks, that are no-go areas for either scientists or seamen. There are no notices saying "keep out"; the atmosphere is just not conducive to visitation.

Now there is, without doubt, good cause for someone to worry about scientist–crew relationships on oceanographic expeditions, one of the most expensive ways of doing research. The memory of the throwing overboard of Antarctic specimens kept in a crew's beer freezer is too vivid for complacency, and the crew of a ship cannot (with a few distinguished, even famous exceptions) be regarded as laboratory assistants or technicians in the land-based sense of the word. But what is really striking on most research cruises is not how the scientists and crew come to some sort of truce, but how deeply the scientists can dislike each other.

The reasons are not difficult to find. It is a certain sort of person who chooses to spend month after month at sea, and yet when he gets there he finds himself in the closest proximity, sixteen hours a day, with a similar sort of person, whose soggy cornflakes at breakfast are likely, in high seas, to end up in his lap. Data collection goes on all night, so each will have regular opportunities to awake the other in an indelicate manner at a hideous hour. Many experiments can only be carried out to the exclusion of all others, leading to endless bickering over the allocation of time. The mixture of disciplines—meteorologists, chemists, geologists, biologists, fluid dynamicist—which (on land, at least) is supposed to be good for science leads to blank incomprehension and a studied inability to see the point of anyone else's work. Some sea-goers work frantically all day and all night and cannot tolerate those who only appear for an hour a day. And one in ten of all oceanographers suffers from seasickness, frequently brought on by ships whose stability seems questionable. In the midst of all this stands the chief scientist, with problems not unlike those of an ice-hockey referee, and with the added complication that captains are always keen to get the ship back to port a day early.

The manifestations of these tensions are often bizarre. There is much practical joking of a pointed sort—a meteorologist may find his cabin completely filled with one of his balloons, and the presence of empty explosives cases allow for some pretty realistic and scary scenarios. The fighting is usually symbolic (water-filled balloons being very popular) but does on occasions end in a punch-up. The presence of so many tape recorders allows the alert discreetly to record the violent arguments that break out now and then, for replay at a quieter time. And accusations about the theft of tools never cease. Every oceanographer takes to sea with him a couple of dozen screwdrivers covered in complex identification marks and yet returns empty-handed and convinced that all his colleagues' locked toolboxes are stuffed with his property. When a research vessel goes to the breaker's yard, out of every crevice must come a screwdriver and a pair of pliers.

Amazingly, this physically unpleasant and emotionally conflict-laden environment not only exerts such a powerful attraction that sailor-scientists come back for more but also seems particularly fertile for the generation of new ideas. The best thinking in oceanographic science is often done on board ship in spare time rather than in the office back home, even though the best reception it is likely to get among one's shipmates is polite boredom. Perhaps a good way to revive some flagging scientific enterprises would be to transfer them lock, stock and barrel to a modest-sized converted trawler, to send them out to the mid-Atlantic and to require them to operate twenty-four hours a day.

There is plenty of sociological research left for the ONR to support. ☐

The little nipper who cost the South a fortune

Colin Norman reports on a threat to call a halt to a long and largely unsuccessful attempt to eradicate the fire ant.

THIS is an account of a fruitless attempt to block an invasion, of political manoeuvrings and fiscal blackmail, of chemical warfare and environmental destruction, and of open dispute between two factions in the federal government. Underlying the whole sorry affair are a variety of scientific issues, but they have generally taken a back seat.

The invasion began in 1918 when a small black ant, known as *Solenopsis richteri*, established a colony near Mobile, Alabama, after hitching a ride on a shipment of fruit from South America. Since then the ant and its red cousin *Solenopsis invicta* has invaded nine states from Texas to North Carolina, resisted a fearful onslaught of insecticides, soaked up $115 million in public money and stirred up a massive controversy.

For the past 18 years, the Department of Agriculture, in concert with the infested states, has been attacking the ants with a variety of chemicals, with the result that the programme has the dubious distinction of being the most expensive single pest-control effort ever carried out in the United States. But last month, Earl Butz, the Secretary of Agriculture, announced that the federal government is finally cutting its losses and will cease bombarding the ants with pesticides on June 30.

The announcement is probably more of a threat than a promise, however, for Butz's statement seems designed to bring political pressure to bear on the Environmental Protection Agency (EPA) to lift restrictions on the pesticide used to attack the ant. "Continuing restrictions placed on the pesticide", Butz said, "have finally made the program completely unworkable", and for good measure he added that the ants "could be totally eradicated with only negligible effects on the environment" if only the EPA were not so diligent in enforcing its regulations.

Officials of the EPA were clearly caught by surprise, for in 1971 the Department of Agriculture decided that for various reasons, including cost, a programme to eradicate the ants was no longer feasible. Future efforts would therefore be aimed at preventing the pest from spreading, the Department said. Nevertheless, Butz's statement has already promoted an outcry in the deep South, and some powerful southern Democrats are beginning to ask questions on Capitol Hill. The battle, clearly, is far from over.

Why has this insect provoked such a costly and seemingly futile campaign? The chief reason is that it has a nasty habit of attacking anybody who comes near it, inflicting a painful sting for which the creature has earned the name of 'fire ant'. It also builds mounds, sometimes reaching a height of about 3 feet, which have hard crusts and present a hazard to farm implements.

About 10,000 people a year were treated in Alabama, Georgia and Mississippi for fire-ant stings in 1969–71. Secondary infections and allergic reactions are the most common problems, although there have only been one or two reports of death from severe allergic reactions—in that respect, the ant is much less of a problem than wasps or bees. A committee which studied the fire-ant problem in 1972 reported that it is "of virtually no importance as a primary pest of crops, livestock or cattle" and in fact it may in some instances be helpful in killing off crop pests. The committee said, however, that the fire ant can harm agriculture by stinging farmworkers, to the extent that they will sometimes refuse to work in heavily infested fields.

The fire ant is clearly a great nuisance, but whether it merits a full scale chemical assault is, however, another matter. In any case, in view of the failure of past efforts to control the ant's spread, Butz's decision to terminate the programme seems like a prudent financial decision at a time when the Ford Administration is trying to reduce public expenditures.

The invasion began slowly at first, encompassing only about 2,000 acres by 1932 In the next 15 years, however, the fire ant had spread to about 2 million acres and by 1959 its territory had widened to 26 million acres. The federal government and the states began their effort to combat the ant in 1957, but the insect promptly responded by expanding its territory to 126 million acres between 1959 and 1969, which makes the anti-invasion strategy about as effective as the federal government's containment activities on the other side of the world. And, like the generals in Vietnam, the field commanders in the fire-ant programme were constantly promising that the end would soon be in sight.

In the early stages, heptachlor and dieldrin were used to bombard the fire ant at a cost of some $2 million a year to the federal government; a similar amount was supplied by the treasuries of the southern states. But, in 1962, the campaign switched to a new weapon—a chlorinated hydrocarbon called Mirex which was reckoned to create fewer environmental hazards and to be more effective than the other pesticides.

Described in one report as having "many of the requirements for an ideal control chemical for the ant", Mirex is applied in very small amounts—about 1.7 g per acre—dissolved in soyabean oil and spread on corn-cob grits. The grits are dropped on to infested fields by aircraft, and are taken up by foraging ants which carry the pesticide back into the mound, where the poison eventually wipes out the entire colony.

Although there had been a few attempts within the federal government to bring a halt to the fire-ant programme during the mid-1960s, the first major challenge came in 1970 in the form of a court suit brought by the Environmental Defense Fund (EDF), a Washington-based environmental organisation. Following reports that Mirex residues had turned up in a wide variety of organisms, particularly crustaceans and other aquatic wildlife, the EDF brought a suit to halt the programme. The immediate result was that on March 17, 1971 the EPA notified the manufacturer of Mirex—the Allied Chemical Corporation—of its intent to cancel registration of the pesticide. That first formal step to remove the chemical from the market was designed chiefly to open up a long investigation of Mirex, which was still going on when the Department of Agriculture made its announcement last month.

The first stage in the investigation was the appointment of a scientific advisory committee, which recommended to the EPA in 1972 that use of Mirex be continued to control the ants. The committee said, however, that the programme should not be aimed at eradication because "the environmental impact of such treatment is too poorly understood and the expense too great to justify a program of such magnitude". The EPA, therefore, decided to prevent the use of Mirex in coastal areas, heavily wooded areas and near inland waters. It also limited use of the pesticide to one application a year. Finally, the EPA began public hearings on the environmental impact of the programme in 1973, and those have been going on intermittently for the past fifteen months.

Although the EPA's regulations merely reflected what the Department of Agriculture was already doing in 1973, it was those restrictions which Butz condemned last month for crippling the fire-ant programme.

Why has the effort dragged on for so long, in spite of little success? The answer lies partly in the complicated politics of the deep South. For one thing, the $68 million that the federal government has so far pumped in to the programme (which has been augmented by $47 million from the states themselves) has provided a welcome addition to the coffers of state agriculture departments. And for another, the programme has powerful supporters in Washington, notably Jamie Whitten, chairman of the House appropriations subcommittee which handles the budget of the Department of Agriculture, and J. Phil Campbell, the Under Secretary of Agriculture. Whitten comes from Mississippi and Campbell comes from Georgia, both of which are heavily infested with fire ants.

Whitten's support for the programme in fact twice saved it from the axe in the mid-1960s, when the Bureau of the Budget tried to eliminate it. Whitten was furious and eventually increased the budget for the programme instead of eliminating it. By 1974, federal funding had passed the $7-million-a-year mark, and the Administration had asked for $9 million for the next year.

About 10,000 people a year were treated in Alabama, Georgia and Mississippi for fire-ant stings in 1969-71. Secondary infections and allergic reactions are the most common problems although there have only been one or two reports of death from severe allergic reactions.

The EPA's surprise at Butz's decision to pull out of the fire-ant programme is evident from a letter sent to Butz by John Quarles, Deputy EPA Administrator, a few days after the announcement was made. Noting that the Department of Agriculture had "abandoned the concept of eradicating the fire ant prior to the imposition of EPA restrictions on the advice of scientists that this effort would be financially and logistically infeasible", Quarles said that the announcement "tends to bring undeserved criticism to [the EPA] when other considerations appear to have played a larger role" in the decision to terminate the programme.

Replying to the letter, Under Secretary Campbell said that "we have chosen to exercise our prerogatives responsibly by suspending the program until we can operate free of crippling restrictions. We ask that, as you exercise your responsibility, you take into consideration that to be environmentally sound, the program must eliminate the fire ant as a pest".

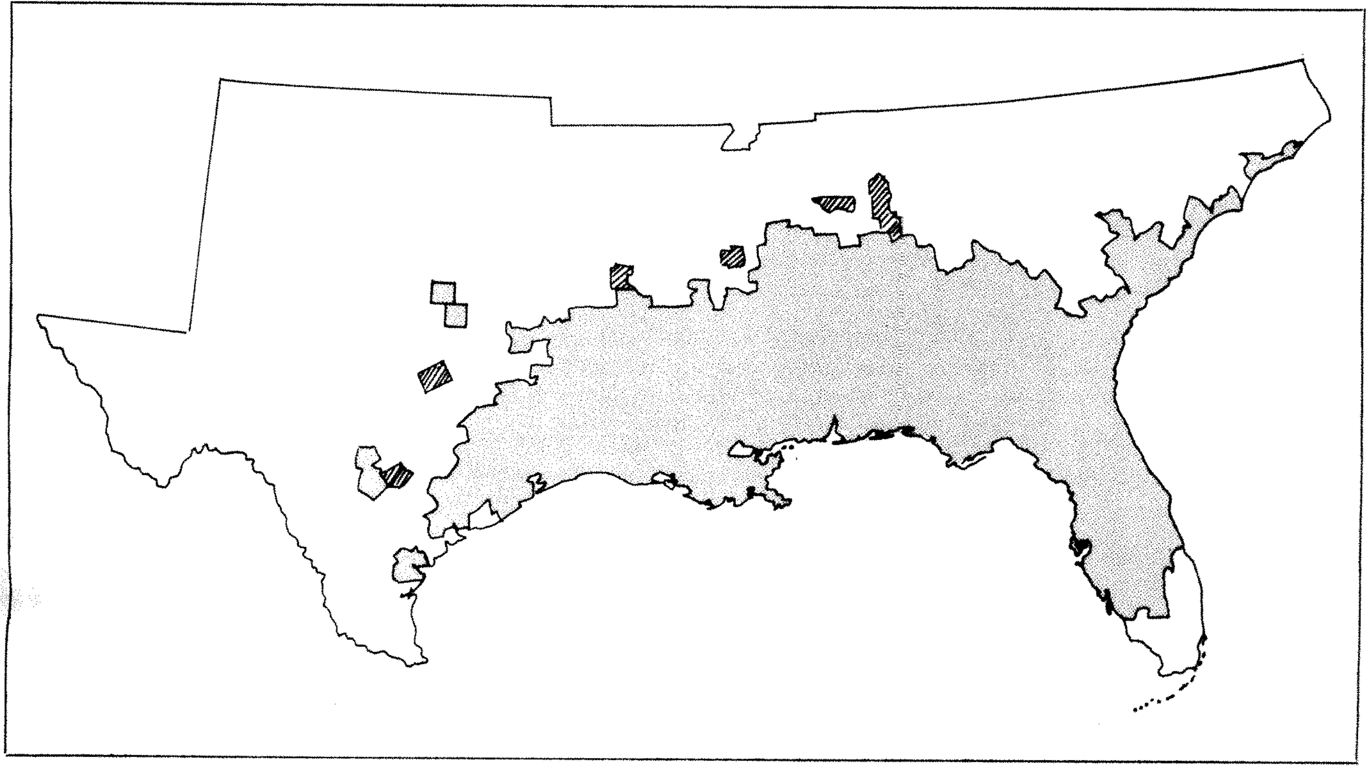
Asked last week what would be required to eliminate the fire ant entirely, scientists at the Department of Agriculture said it would probably take three applications of Mirex in an eighteen-month period over the entire infested area, including coastal regions. Since the federal government last year spent about $1 per acre on the programme, complete eradication would run into hundreds of millions of dollars.

The department's belief that eradication is possible is based on three large-scale trials carried out in Georgia, Florida and Mississippi in 1967, where almost total eradication of the ant was achieved after three applications of Mirex. Opponents of the programme point out, however, that the areas rapidly became reinfested, and that if such a programme is carried out on a larger area, the potential destruction of non-target species would be very large.

Nevertheless, Butz's decision has been greeted with dismay in the infested states, which have been relying on federal support for their efforts to control the ant. Typical of such reaction is a letter sent by the commissioner of Alabama State Department of Agriculture to Representative William L. Dickinson. "To deprive the inhabitants of the infested states of the program which gives some relief from the Imported Fire Ant is reprehensive [*sic*]", the letter stated.

It is unlikely that the plea will go unheeded in Congress, but exactly what will transpire is, at this stage, highly uncertain. □

Shaded area: generally infested area (eradication treatments not in progress or planned). Hatched areas: ant eradicated, and regulations removed.



Poisons, and how to dump them

The growth of concern about the tipping of noxious and toxic wastes in the UK has taken place against a background of increasingly tough legislation, the programme for which has nonetheless now come to a temporary halt as the result of a tight economic situation. John Newell reports.

DURING the next few months, the first reports are expected to emerge from technical groups within the Department of the Environment's waste disposal section. These groups are looking into the best ways of disposing of specific toxic wastes, including arsenic compounds, acids, mercury and other heavy metals in various concentrations, tarry residues and metal-finishing wastes.

Recommendations will take into account the 1974 Control of Pollution Act, which allows stringent requirements to be laid down for the disposal of particularly hazardous wastes. As soon as the Act comes into effect, all private operators will have to apply for licences for sites used to dump all noxious wastes. The power to withhold or remove licences, and the power to prescribe special codes of practice for especially toxic wastes provides local authorities with two powerful new safeguards. Nor do they any longer have the burden of proof of damage to the environment, as was the case under the 1972 Disposal of Toxic Wastes Act.

The 1974 Control of Pollution Act, the implementation of parts of which has been delayed for at least a year, goes further than the 1972 act in making it a duty for each local authority to make a survey of all industrial and domestic wastes created in its area. Local authorities must make detailed plans for the disposal of all wastes, and are compelled to introduce a licensing system for both landfill disposal sites and waste disposal operators. Local authorities will also be required to set out and maintain equivalent conditions for their own refuse disposal operations.

Although industry has welcomed the new act in principle, and has also supported the development of chemical treatment plants and modern incinerators, the economic situation has meant that the actual usage of such plants is somewhat disappointing, especially where smaller companies are concerned. But the implementation of the 1974 act should help those companies by ensuring that adequate disposal facilities are provided by local authorities.

For the foreseeable future, all existing means of disposal of toxic waste are bound to continue in use. The more recently designed chemical treatment plants for toxic wastes have, however, been designed with a view to increasing substantially the small proportion of their input which is at present recycled. Re-Chem International (which build chemical treatment plant) estimates that about 1 million tons of hazardous waste are produced annually in the UK, and this is thought to be increasing by about 1% (10,000 tons) a year.

The present need to restrict local-authority expenditure is inevitably delaying the timetable for bringing the act into full operation. Nonetheless, the parts of the act requiring local authorities to survey all waste, products and those concerned with the introduction of increased penalties for existing pollution offences, are being introduced over the next few months, as they require little or no extra manpower.

On the other hand, the requirement to produce a formal waste disposal plan has been deferred for a year, after discussion with local authority associations, and so also has the requirement to introduce the licensing system. The parts of the act relating to water pollution will also be implemented in phases starting next year.

The fact that the act is now on the Statute Book is, however, already causing alterations in waste disposal practice in preparation for what is to come. Landfill will remain the principle means of disposal and the Department of the Environment has had a research programme on landfill with toxic waste running since 1973. One aim is to produce a code of practice for use by waste disposal authorities in the selection and control of disposal sites. The code will be concerned with water pollution and atmospheric pollution hazards, odour nuisance, and contamination of soils and vegetation. The team involved is developing a mathematical model of the behaviour of hazardous materials in the interiors of landfill tips.

Sheer shortage of tipping space is already encouraging the recycling and reclamation of ordinary household rubbish and this will probably soon be the case for actively toxic wastes, too. The Department of the Environment points out, justifiably, that the 1974 Control of Pollution Act has been the model for an EEC policy directive and that UK legislation in this field is ahead of most of the world. But the pressure in the future seems bound to be directed towards more incineration, more chemical treatment to render harmless, and more active recycling of toxic wastes. □

Foetal research ban to end

by Colin Norman, Washington

A PRESIDENTIALLY appointed commission will recommend later this month that the federal government should lift its moratorium on funding for research on living foetuses In place of the moratorium—which was imposed by Congress last year—the commission will recommend a set of stringent controls to ensure that such research is carried out according to strict ethical guidelines.

The commission's recommendations, which were agreed at a public meeting late last month, will be sent to the Secretary of Health, Education and Welfare along with a report providing justification for them. The secretary must either use the recommendations to draft regulations governing federal support of foetal research, or state publicly why he cannot accept them

The commission—the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was established by Congress last year and was given four months in which to draft regulations governing foetal research and two years to draw up recommendations governing other types of human experimentation. The recommendations are, however, far from being the final word on the matter, because foetal research has unfortunately become ensnared in the loud and bitter dispute over abortion which has been raging in the United States for the past couple of years. The anti-abortionists are unlikely to accept the commission's recommendation.

The commission decided, in short, that therapeutic research, designed to benefit either the foetus or the mother, should be actively encouraged by the federal government, but that all foetal studies should be subjected to review procedures at the local level. One review committee would ensure that the study is ethically acceptable and likely to produce worthwhile results, while another would monitor the experiment to ensure that it is conducted according to ethical guidelines The mother's consent, and if possible that of the father, would also be required before any research on living foetuses could be conducted.

The two most controversial areas of foetal research—those involving studies of foetuses which have been scheduled for abortion but which are still in the womb, and experiments on living, but non-viable foetuses after they have been aborted—would require prior review by a national ethical review board, the commission suggests. Examples of the first category are the administration of drugs to pregnant women about to undergo abortion, and subsequent examination of the foetal tissue to see whether the drug crossed the placenta. Four researchers are, in fact, awaiting trial in Boston on charges arising from such an experiment. And the second type of research includes, for example, studies of foetal circulation.

Although the commission's recommendations are likely to play a vital part in the development of policies governing federal support of foetal research, they have already been made largely redundant in some parts of the United States. Biomedical researchers conducting some types of foetal studies in those places face stiff prison terms, and so for them the question of whether or not the federal government would support their research is entirely academic. ☐

ALTHOUGH it is common practice for elders of the scientific community to lament the decline in federal support for science, and to warn that the fabric of scientific research will be irreparably damaged unless the government adopts less parsimonious policies, a recent speech along those lines by Philip Handler, the President of the National Academy of Sciences, is drawing considerable attention.

Delivering his annual report to the academy last month, Handler noted that "there are scattered clouds on the science horizon" which include lack of growth in the science budget, threats to the peer-review system by which grants for basic research are awarded, and a "bookburning" attitude in Congress

Proceeding from the observation that the Ford Administration's budget for next year is essentially a "no growth" budget for basic research, Handler drew attention to the fact that "there are continuing pressures to maximize the use of available federal resources for the support and conduct of that science which promises earliest applicability". In particular, he suggested that "support of basic research by the Defense Department becomes increasingly constrained", and "emphasis on specific applied programs using funds formerly available for free research is a matter of policy at the National Institutes of Health, particularly the National Cancer Institute".

Those complaints are standard fare, but Handler suggested that "other factors loom as more worrisome", and "one can see in the offing a powerful threat to the peer-review system for decision making with respect to selection of research projects for support". The threat comes from the recent spate of press releases, emanating chiefly from the office of Senator William Proxmire, which have poured ridicule on science projects with trivial or funny-sounding titles. Such tactics, which are designed chiefly to generate cheap publicity, have planted in the public's mind "the seed of distrust in the judgement-making apparatus", Handler suggested.

Such distrust caused the House of Representatives last month to pass a preposterous amendment to the authorisation bill for the National Science Foundation to give Congress veto power over every individual grant awarded by NSF. Although the Senate is unlikely to follow suit, Handler noted that "the point is that the House came dangerously close to passing an amendment which was tantamount to bookburning". He continued, "the intrusion of political considerations in the award of grants by an agency whose principal purpose is to support the continuing dispassionate search for truth and to support education in that knowledge which has been gained by rigorous investigation according to the highest canons of our disciplines, is unacceptable". The House's action, Handler said, "is a giant leap backward by a supposedly egalitarian House which adopted a procedure appropriate only to authoritarian regimes".

Handler urged the scientific community to come to the defence of research projects that are subjected to attacks from Senators and Congressmen in search of publicity because if such projects "are not defended by all of us, it will be our turn next".

Soviet rocket puts India in space club

by Narender K. Sehgal, Jullundur

FOR the second time in less than twelve months India has forced her way in to an exclusive club, some of whose members happen to believe that she has no business being there in view of her poverty and food problems. First, it was the nuclear club on May 18 last year and then, on April 19, 1975, India's first ever satellite was successfully launched on a Soviet Intercosmos rocket—making her the eleventh member of the space club.

Prominent members of the scientific community have expressed happiness at the accomplishment. "This is another proud day for all Indians", said Dr M. S. Swaminathan, President of the Indian Science Congress Association, in Calcutta. Nearly everyone, while expressing satisfaction, said they were looking forward to the day when an Indian satellite would be launched from within India itself.

Named Aryabhata, after the famous Indian astronomer-mathematician of the fifth century AD, the blue and violet, 26-faced, diamond-shaped satellite weighs 360 kg and is orbiting the Earth every 96.41 minutes at an altitude varying between 564 and 623 kilometres and an inclination to the equator of 50.4°. The operational life of Aryabhata is estimated to be about six months, because that is how long the stock on board of an inert gas (used in the spin-up stabilisation mechanism of the satellite) will last. But the satellite is expected to stay up in orbit for about 2½ years. Aryabhata is equipped to carry out three scientific experiments during its operational life. One experiment, designed by ISRO (Indian Space Research Organisation) scientists themselves, will make X-ray measurements; another designed by the Tata Institute of Fundamental Research, aims at detecting high energy neutrons and rays at times of intense solar activity; and the third experiment, set up by the Physical Research Laboratory at Ahmedabad, will study electrons in the ionosphere and ultraviolet radiation in the night sky.

Work on Aryabhata began following an agreement between ISRO and the USSR Academy of Sciences in May 1972. (The USSR help was sought only for the launch.) The Indian Scientific Satellite Project, established by ISRO in December 1972 at Peenya near Bangalore, was given the overall responsibility for fabrication of the satellite. But the final product was the result of a collective effort by nine major institutions, including national laboratories, private and public sector undertakings and a number of small scale industries. The flight model was designed and fabricated indigenously and tested extensively both at Peenya and in the Soviet Union. Only certain components—the solar cells, chemical storage batteries, sophisticated onboard tape recorders and spin-up gas bottles—had to be obtained from the Soviet Union. Some 'space-qualified' electronic components, too, had to be imported from abroad because they were not available in India. The laboratories at Peenya included the space simulation chambers for testing the various sub-systems of the satellite. The chambers were designed and built by ISRO engineers in collaboration with the Bhabha Atomic Research Centre at Bombay and the Electronics Corporation of India Ltd at Hyderabad. The design and fabrication of instruments for commanding the satellite from ground stations at Sriharikota in Andhra Pradesh and Bears Lake near Moscow were also carried out by Indian scientists and engineers. The entire Aryabhata project cost Rs 43 crores (= Rs 43 million), including the infrastructure and facilities that went into creating it, and was executed in 30 months.

With this feat, the inevitable cropped up again. Among the first questions that the Prime Minister Shrimati Indira Gandhi and the Chairman of the Space Commission, Professor Satish Dhawan, had to face were variants of the following: "Why has India chosen to spend money on a space programme? How does Aryabhata fit in with the country's development priorities? Will there be any returns from these investments? Will they justify the monies and efforts expended on them?"

Fortunately these questions did not seem as difficult to answer as the ones posed about the nuclear explosion last year. For one thing, the objectives of Aryabhata are certainly not as controversial. Second, India has already been making use of foreign satellites, among other things, for communications. Moreover, a major educational experiment SITE (Satellite Instructional Television Experiment), to be launched in July this year, will make use of the American ATS-6 satellite for a year to beam television programmes in regional languages to receivers in several thousand villages in selected states.

Scientific and technological self-reliance is the under-lying theme behind the space programme, as is also the case with India's nuclear effort. The Indian government happens to believe that the nation's economic and social well-being will be helped by keeping abreast of the latest advances and developments in various scientific and technological fields. India, with the third largest scientific and technological personnel force in the world next only to the USA and the USSR, intends to make fuller use of space technology in the fields of communications, television, meteorological studies, earth resources, agricultural crop surveys and so on. Specifically, Aryabhata is designed as India's first step towards establishing her own capability in the area of satellite fabrication. The three scientific experiments, though important and "most modern" in the words of Academician Boris Petrov (Chairman of the "Intercosmos", the Soviet organisation in charge of international cooperation), are only of secondary importance; the mission would be considered successful if all systems aboard Aryabhata function normally, irrespective of the experiments. Happily, first indications are that all instruments and equipment aboard the satellite are working normally and well.

As a next step, Aryabhata 2 may be launched soon It will carry television camera systems to survey mineral

---

THE Swedish and Russian Academies of Science have concluded an agreement on exchange of researchers and research. The agreement is unique in that, unlike the others the Russians have with western countries, it allows for the host country to invite specific scientists by name for study visits rather than accepting the other country's nominations. Each country will have 60 man months a year of expertise from the other, and the main areas of exchange are expected to be biology, physics and chemistry.

The agreement formalises and broadens already existing cooperation between Russian and Swedish scientists. Professor Hans Vilhelmsson at the Chalmers Institute of Technology, for example, has already had fruitful exchanges with Russian researchers in plasma physics. Last year he invited four specific Russians to a workshop at Chalmers. All came, and the meeting produced reports to be published soon in *Physica Scripta*.

Upholding the individual invitation clause will of course depend on goodwill between the scientific communities in each country and also on the Soviet government. There is plenty of goodwill at the moment, and an obvious incentive for the Russians at least to maintain theirs. For who knows what visiting Russian scientist may impress his Swedish hosts so much that they award him a Nobel prize. —*Wendy Barnaby*

Ice on troubled waters

from Vera Rich, London

THE new Soviet icebreaker Arktika has received, throughout her construction, the continuing press coverage reserved for major Soviet prestige achievements —interviews with the designers, scientists and research teams and a number of extensive, but often peripheral, articles related to the history of nuclear-powered icebreakers. To enhance this aura of prestige, the commissioning date of the Arktika was apparently chosen with an eye to symbolism: the hammer-and-sickle was hoisted on the new flagship of the icebreaker fleet "on the eve of May Day and on the threshold of the thirtieth anniversary of the victory over Nazi Germany".

Yet the Arktika and her sister icebreakers, which can extend the navigation season of the Northern Sea Route by several weeks each year and which undoubtedly rank as a major Soviet achievement, may well mark the quiet demise of an even more spectacular achievement *in spe*—the diversion of the Siberian rivers. This concept of a super-irrigation scheme, by which the waters of the Ob' and Yenisei would be "turned backwards" (conveyed by a series of canals to irrigate the deserts of Soviet Central Asia and, by way of the Volga. to replenish the shrinking Caspian) has been a dream of the Soviet planners for many years. The waters of the Ob' and Yenisei would no longer spill wastefully into the Arctic Ocean, but would have their directions of flow reversed, to the benefit of Soviet agriculture and the Soviet economy.

But now, likewise in the name of the Soviet economy, the construction of an icebreaker fleet implies another use for these waters. The home port of the fleet, Murmansk, is normally ice-free throughout the year. Some 1,500 miles eastward, however, lies the new mineralogical centre of Noril'sk, producing rich ores of non-ferrous metals. The only practical outlet for the products of Noril'sk, and the only means of providing its 150,000 inhabitants with essential supplies, is the rail link to the port of Dudinka on the Yenisei, and thence by river and across the Kara and Barents seas.

This river and sea route is normally blocked by ice for seven or eight months of the year. During these months, large icebreakers, such as the Ermak, the Lenin and now the Arktika must force a way through the ice for the freighter convoys. But these large ships (the Arktika is 140 m long and 30 m wide) can only operate between Murmansk and Dikson at the mouth of the Yenisei gulf. To conduct the convoys on the river route to Dudinka, "medium power" icebreakers (presumably with conventional engines) must be used.

If the Yenisei diversion scheme is still at the forefront of Soviet development plans, it would seem logical to assume that these smaller icebreakers are an interim measure and that, in the fairly near future, they will be replaced by a rail link from Dudinka to Dikson (which could, itself, rightly be considered a prestige achievement). This, however, does not seem to be the case. According to a *Novosti* release of March 10, "new up-to-date icebreakers with a small draught and able to negotiate the Yenisei are under construction". Although it is difficult to project the expected lifetime of these small-draught vessels, taking into account considerations of cost-effectiveness and the time still needed for construction, it would seem that the planners of the Northern Sea Route envisage that the lower reaches of the Yenisei will remain "navigable" (at least to icebreakers) until the end of the century. Which poses the problem: what becomes of the diversion scheme? Has it been quietly relegated into the sphere of plans that are desirable but not, within the foreseeable future, feasible (although still, from time to time, receiving the occasional tribute of press coverage?) or is there some lack of communication between the two planning bodies concerned—a division of interests, each demanding the use of the waters of the Yenisei in the service of the Soviet economy but pulling, literally, in opposite directions?

deposits and agricultural crops. The satellite—actually a back-up model for the one now in orbit—is reported to be almost ready. Encouraged by the success of its maiden venture, ISRO intends to begin negotiations soon with the USSR for a fresh agreement to launch it.

Satellite fabrication is only half the story however, as far as self-reliance is concerned. Work has also been in progress on a four-stage satellite launch vehicle at the Thumba rocket station in Kerala. But because of a shortage of funds, the project is running several years behind schedule. Moreover, it will only be able to launch a small payload weighing no more than 40 kg to start with—a mere ninth of the weight of Aryabhata.

It is just as well that the first Indian satellite was not launched from Indian soil, for possession of a rocket powerful enough to launch a satellite hundreds of kilometres into space would have most certainly been seen by critics aboard as an effort to develop an intermediate range ballistic missile capability. But here in India, one can discern no indication of any such attempt, if one goes by the small sums of money earmarked for the space and nuclear programmes—and the fact that the military has been kept well away from these programmes, almost to the extent of deliberate exclusion.

Notwithstanding hostile criticism abroad, there are many in India who believe she should keep all her options open, nuclear weapons and all, even if she does not intend to use them. A technical commentator for a national daily newspaper recently deplored the almost total lack of coordination between the nuclear and space programmes, on the one hand, and the military establishment on the other. He concluded thus: "Viewed from nearby and even with the bias natural to any one with the country's interest at heart, we are far from a nuclear weapons capability. Both the atomic energy and space research budgets are pegged at low levels. They cannot sustain a military capability in nuclear weapons. However, research projects must not, by deliberate choice, exclude the full range of applications of research achievements. Since both atomic energy and space research programmes are doing so, at least in the military field, Indian planning could do with some redirection, even at the risk of inviting further criticism overseas." ☐

US university R and D

THE US National Science Foundation has published a set of figures chronicling the decline in federal support for research and development in universities in the United States. NSF's figures show that total spending on research and development in higher education increased from $2.900 million in 1973 to about $3,000 million in 1974 which, when inflation is taken into account, represents a drop of about 5% in purchasing power. Within that total, however, federal support declined by 8% in constant dollars. Part of the decrease is explained by a book-keeping change involved in the transfer of the Draper Laboratory from the Massachusetts Institute of Technology into the independent non-profit sector, but even taking that into account, NSF points out that the purchasing power of expenditures on academic R & D declined by 3% and federal support declined by 6%. ☐

Great Lakes report

from Angela Croome

CANADA and the USA share in the ratio of about 2 : 3 the most extensive and one of the richest bodies of freshwater in the world—the Great Lakes system which consists of five lakes with a total surface area of 94,250 square miles. Not only are the lakes themselves large and valuable but they are surrounded by a region of gentle topography, temperate climate, vast mineral resources and bountiful farmland. Through the St Lawrence Seaway, opened in 1959, the lakes serve as a direct water link with the rest of the world, bringing ocean shipping to the heart of North America. As a result the system forms the hub of the North American population, with nearly 35 million people living in or near the Great Lakes Basin (one in every three Canadians, and one in every eight US citizens); predictions for the end of the century suggest a doubling of these figures.

When they were first discovered the vastness of the Great Lakes made them seem indestructible compared with the works of man. No longer. Their increased use, and rising industrialisation and population around their shores, makes the lakes system seem fragile in the face of man's multifarious interventions. Indeed they have proved so. Lake Erie was declared eutrophic some years ago. Both Lakes Michigan and Ontario have ceased to be safe for swimming and both have suffered serious algal blooms and fish-kills. Yet there is still a need to stretch the lakes' capacity to meet a swelling demand from the human population.

With the specific object of improving management of the Great Lakes as a whole to meet this demand, Dr D. V. Anderson, of the University of Toronto, proposed an International Field Year for the Great Lakes (IFYGL) as North America's principal contribution to the International Hydrological Decade which supposedly ends in 1975. Lake Ontario was chosen for this intensive study, because it is the smallest of the five (7,340 square miles) yet typical of the others (excepting Erie), convenient to study, situated in a growing population area and already showing signs of deterioration. The concept was that most of what was learned from the intensive study of Lake Ontario would be applicable to the other Great Lakes and even to other large lakes throughout the world. The project was delayed because of difficulties encountered in the USA, first in finding a 'lead' agency and then in obtaining the money for research. (Canada, with its centralised national research council structure and funding, was readily able to provide support by simply adding to ongoing projects.) The budget of $35 million called for was eventually collected and the IFYGL was initiated in April 1972.

Curiously there had been no co-operative agreement between the USA and Canada on protective and restorative measures until that date. In the rider to the agreement then made, the point was made that although the technology for repair was adequate, solutions to many of the problems could not be prescribed because knowledge and understanding of the various interactions within the systems are "woefully inadequate". Before the Field Year there had been plenty of individual scientific projects going on but there was no overall view taken. The six 'core' programmes selected—lake meteorology, energy balance, terrestrial water balance, lake water movement, biology and water chemistry—were intended to provide the data for sound solutions and wise future management. The publication of the preliminary batch of reports provides some opportunity to judge how successful this has been. Water quantity and water quality lie at the root of all the problems of the Great Lakes. The first shows up in such problems as flooding, eroding shorelines, low water in ship canals, storm damage to coastal facilities and cutbacks in production at the numerous hydroelectric plants. There is, in addition, the ice nuisance which both precludes inter-lake navigation in winter and often severely restricts the flow of water to the hydroelectric power stations. It has been suggested that waste heat from the increasing number of thermal electric stations be used to melt the ice, but this is a step to be taken only after weighing up all the other factors. Problems with water quality include sewage pollution, safe water supplies and, particularly important for Lake Ontario, the collapse of commercial fisheries. The unforeseen migration of alien species such as 'alewives' and parasitic lampreys from the Atlantic up the navigation canal network has played havoc with favoured game fish though overfishing met this menace half-way.

As it happened spring 1972 to spring 1973 was atypical in one respect: the weather. It was the wettest 12 months for years. Moreover on the basis of 30 years of records the driest month of the year is usually June but in the Field Year it was the wettest (by a factor of nearly two). Not surprisingly, the inflow and outflow to the lake was also abnormal, with the July runoff four times higher than usual. Whereas pathways and balance could be studied, the normal hydrological cycle was hardly manifest. The arrival of Hurricane Agnes during some days in June however, provided a bonus in the form of a thorough check of the reliability of rainfall radars. It was found out that the radars underestimated the volume of rain by as much as 40% and the errors were particularly marked when the heaviest rain occurred. Inadequate warning of floods is attributed to the radar errors.

A special study of the lake–atmosphere boundary layer by several means was incorporated in the programme partly because of the increasing interest this interface is attracting and partly because Lake Ontario offered a convenient site on almost a 'sea' scale. Preliminary results indicate that a large fraction of the annual evaporation occurs in a very few intense, cold-air outbreaks in autumn and that on these occasions there is an extremely large gradient of evaporation across the lake. A further curiosity identified by this programme was the occurrence from time to time of a wave-driven wind on the lake. (Some wave model studies carried out in 1966 had suggested that such a phenomenon might exist.) Specific studies of airborne sulphur dioxide contamination blowing in near Niagara (calculated to amount to several tons a year) showed that a lake with a *p*H near 8 may act as a very effective SO_2 'sink' for the atmosphere.

The study of fish population, which is of major significance to the Canadian authorities as they are in the midst of attempting to restore the ravaged Lake Ontario fish stocks, was specifically aimed to be a first step in a continuing programme to guide lake management. Collections of fish were made over the whole lake in all seasons except winter. A total of 63 species was collected and produced few surprises. Samples did, however, include a few deep water sculpin (thought to have been extinct) but no examples of the equally popular indigenous cisco. Introductions, the American smelt and the alewife, dominated the main trench and were also common pelagically. The authors end their paper with a heartfelt comment that "ecology is poorly understood in the physical aquatic sciences". This work is now a continuing 'core' programme for the Canadians, who hope eventually to defeat the invading lamprey and return their lake to full health and fish production.

THE constantly growing world shortage of non-human primates for research laboratories, which has already held up some Israeli immunological and pharmacological studies, will apparently lead to the development of a new branch in the economy of several kibbutzim—the raising of monkeys on a commercial basis. Such a scheme has been in the air since the early 1970's when the National Council for Research and Development sponsored a feasibility study. But it was rejected three years ago because it was still cheaper at that time to import non-human primates from countries in Latin America, Asia and Africa (where they only had to be trapped) than to raise them in captivity, in itself a risky venture.

The cost of monkeys on the world market has, however, significantly increased in the interval and, more important, they are not always readily available even for buyers willing to pay the ruling prices At the same time, a number of kibbutzim have succeeded, without fanfare or official sponsorship, in raising such animals on a modest scale. Local collective settlements originally brought in monkeys for their special educational farms, where kibbutz children cultivate crops and raise animals on their own, with a minimum of adult supervision. Most of these primates adjusted well to kibbutz life and in some cases even multiplied.

Thus it was natural for Israeli primatologists to view the kibbutzniks as potential partners in a scheme to raise non-human primates on a larger scale for local laboratories and perhaps for export. Initial plans call for the creation of several pilot centres, in places ranging from the relatively cool Galilee to the sometimes very hot Negev. Their first inhabitants will be rhesus, vervet and squirrel monkeys, the progeny of which, if all goes well, will be available for marketing in 1978.

It will be a long time before the kibbutzim can produce enough monkeys to meet the requirements of local laboratories (about 500 animals a year at present), let alone have a surplus to sell overseas. But if the scheme proves successful, it will be of great benefit to research scientists here as well as a welcome source of income for the kibbutzim, particularly since kibbutz children will do most of the routine work that does not involve physical contact with the animals.

There is however, still some opposition to be overcome at the settlements themselves One kibbutz teacher, for example, is concerned with the possibility that raising the primates will create educational problems "It is well known that many monkeys in captivity spend a great deal of time masturbating in their enclosures. How", he asked me in great bewilderment, "am I going to explain that to my first graders?"

- Links exist between Israel's kibbutzim and her institutions of research and higher learning on many levels. Blessed with a highly intelligent population, the settlements are quick to use research results relevant to their industrial and agricultural branches, as well as to their educational system. Moreover, some 2,000 university students and almost 100 university faculty members are from kibbutzim.

Letter from Israel

from Nechemia Meyers, Rehovot

HEATH
DO NOT WATCH THE MONKEYS

Although few participants were aware of the fact, the man who organised this month's EMBO Workshop on muscle cell culture in the study of gene expression during differentiation, Professor David Yaffe, of the Weizman Institute is a member of Kibbutz Givat Brenner. This same collective settlement boasts yet another Professor at the institute, Achi Brandt, the mathematician. Head of the Pure Mathematics Department, Professor Brandt contributes not only his salary but also his know-how to the kibbutz, helping it to use computers in planning the most efficient exploitation of its manpower and production facilities.

As Brandt recently explained it: "To establish the best method of distributing kibbutz resources. you must first assess the possible economic activities, their income and cost, and the availability of such components as manpower, land, capital and water. At the same time, you cannot overlook tricky agro-technical, seasonal and even ideological restrictions (such as the desire of most kibbutzim to minimalise or, if possible, eliminate the 'exploitation' of hired labour in kibbutz fields and factories). With these data, the optimal plan can be found by a properly designed computer program which can also tell us the relative importance of each restriction imposed on the system."

Brandt even showed his fellow kibbutzniks how a computer could be used to help the settlement reach decisions on social issuses. "For instance", he told me, "we have long had a fierce dispute as to whether our children—who now all sleep in what we call children's houses—should not perhaps sleep at home with their parents. So I devised a questionnaire to sift out actual needs from mere opinions, and wrote a program which analysed the answers. We discovered that, quite contrary to what we thought, only a minority of kibbutz parents really feel that their children should sleep at home. At the same time, this minority wants to change very badly, so that some modification in the system may very well occur at Givat Brenner as it has at other settlements."

- The unique ethnic character of Israeli kibbutzim has long attracted the interest not only of the sociologists and anthropologists but also of medical researchers, who welcome the opportunity to measure the positive and negative effects of life in Israel on the health standards of various communities. Some years ago they discovered for example, a clear link between the onset of Westernisation—particularly the adoption of Western eating habits—and an increase in the incidence of heart disease and diabetes among Jews from Yemen, who, before their emigration, had lived in a 14th century society and subsisted on a virtually fatless and sugarless diet. As they began eating more fats and sugars, they grew increasingly prone to heart disease. Of course one shouldn't overlook the fact that their life expectancy here is still much higher than it had been in Yemen, where modern medical care was unobtainable.

Now the same pattern has developed among the Bedouin. Doctors at the Negev Centre Hospital in Beersheba, where hundreds of Bedouin are treated each year, report a steady increase in heart disease among them, even though it still remains much lower than among the Jewish residents of the area. But, as with the Yemenites, overall life expectancy has risen to West European standards (70+ for males), by comparison, for example, with 50 years in neighbouring Egypt.

Israel's best known ethnic malady is Tay-Sachs Disease, a fatal genetic disorder limited almost entirely to infants whose forebears came here from certain parts of East Europe. Although the disease is still incurable, Israel—like Jewish centres in the USA and Canada —has instituted a Tay-Sachs screening and counselling programme to advise potential parents whose offspring might be affected.

Jews from Oriental lands also have their 'own diseases', one of which—favism—was responsible for a completely unnecessary mini-panic here recently. The hereditary disease strikes people who lack a particular enzyme (G6PD), one which protects red blood cells against the noxious effects of the fava bean and other materials, and thus prevents anaemia. It is by no means limited to Jews, as it affects, among others, Scandinavians, American Negroes and groups in South-east Asia. But among Jews it is limited almost exclusively to people who have lived in Iraq, Kurdistan or Iran.

In spite of this well established fact, the Ministry of Health last week dramatically announced that all Israelis should refrain from eating fava beans (which, together with common medicines like sulpha drugs and aspirin, trigger favism). The sale of fava beans diminished, of course, but rose again when citizens were informed that unless they came from those three countries they could eat the lentils to their heart's content. A screening programme now being carried out at local hospitals should clarify the problem for all Israelis in the course of the next few years.

- The dangers of inbreeding within a particular ethnic group are starkly emphasised by the problems facing the Samaritans, an ancient Holy Land sect which now numbers some 450, half of whom live in Holon, a suburb of Tel Aviv, while the other half live in the West Bank town of Nablus. Becaus 58% of Samaritan marriages take plac between members of the same famil an abnormal number of physically o mentally handicapped children is bor to members of the community. Ne blood in the form of five Jewish bride has improved the genetic mix in recen years, but the community still remain dangerously inbred.

Yet these people, descendants of th Good Samaritan, show an extraordinary will to survive. They no number more than three times a many as they did a hundred years ag when *The Times* reported that ther were only 135 Samaritans in the entir country. □

Mediterranean mercury

SIR,—The article by Alexander Dorozynski (April 17) on the "Mediterranean poison fish forecast" made by Dr Maurice Aubert, Director of the Centre d'Etudes et de Recherches des Biologie et Oceanographie Médicale in Nice states that more than 1 p.p.m. of methylmercury is present in nine species of fish caught in the Mediterranean. There is a calculation attributed to Dr Aubert worth quoting: "Since it has been found that only 4 to 5% of mercury absorbed is fixed in the organism, the weekly absorption of food containing 2 mg of mercury will result in a fixation of 80 μg. At this rate the lethal dose is reached about 20 years". The lethal dose according to Dr Aubert is 80 mg, which is reached in the fisherman by the following equation:

$$2\ \text{mg} \times 0.04 \times 52 \times 20$$

This calculation has no scientific basis. First Japanese data indicate that 80 mg is the lowest toxic body burden and not the lethal dose. Second abundant data reviewed by expert committees show that approximately 95% of the ingested methylmercury is absorbed from the gastrointestinal tract and that the average half life of methylmercury in the human body is 70 days. This means that the body burden of the fisherman in question will be 24 mg after 6 months, 28 mg after 1 year and 28.86 mg in the steady state when he will excrete exactly 2 mg of mercury a week.

The same criticism applies to Dr Aubert's calculation for the child victims of Minamata. He also misquotes the lowest level of hair mercury associated with intoxication. According to the work of the Swedish Expert Group on the Minamata epidemic, 60 μg/g Hg signals the danger of intoxication rather than twice the level (7.39 μg/g) found by Dr Aubert in a fisherman. Based on the relationship between the concentration of mercury in hair, the blood level, the body burden and the weekly dose, his fishermen probably had a body burden of less than 10 mg, which assuming steady state conditions was the result of the weekly consumption of 0.7 mg mercury as methylmercury.

Yours sincerely,
L. MAGOS

MRC Laboratories,
Carshalton, UK

In line 9 of paragraph 5 of the article, 25 μg should read 25 mg.

Plants

SIR,—Rain forests, vanishing wild life and the destruction of rare wild flowers by reservoirs are all sure of space in periodicals and funds for conservation on grounds of preserving the gene pool, yet garden varieties of vegetables are in greater danger of extermination. The FAO are now searching Turkey for hardy varieties still grown by peasants, but Europe is destroying her genetic heritage from the best of motives.

Modern methods of seed storage make it possible to keep packets "in mothballs" for as long as 200 years and I suggest that stocks of all deleted varieties should be donated to a National Seed Library, ideally sited at a University such as Reading, from which they would be available to plant breeders and enthusiasts. We would be glad to hear from those who are seriously interested in this project an from Foundations and others wh would make grants to start a Worl Vegetable Fund, like the World Wildlife Fund, but more urgent in view o the greater pace of extermination.

Yours sincerely,
LAWRENCE D. HILLS

news and views

Chinese work on insulin

from Dorothy Crowfoot Hodgkin

Two very beautiful papers on insulin appeared in *Scientia Sinica* in December 1974 (**17**, 752 and 779). They continue a sequence of scientific publications which began in 1961 and includes the total synthesis of sheep insulin, described in 1965. They are published by groups of research workers in China: in Peking in the University (Departments of Biochemistry and Organic Chemistry) and in the Institute of Physics of the Academia Sinica, in Shanghai in the Institutes of Organic Chemistry, Biochemistry and, most recently, Zoology. They provide impressive evidence of integrated researches in different disciplines and laboratories.

The first of the present two papers describes the derivation of an electron density map of insulin in rhombohedral 2-Zinc insulin crystals at 1.80 Å resolution. It gives useful experimental details of the preparation of the crystals and heavy atom derivatives, of the measurement and interpretation of the X-ray diffraction data and of the stages of solution of the structure. The model and electron density map (clearly of very good quality) are illustrated in colour and the atomic arrangement is described in detail. Ramachandran plots and a plot of the distribution of $C\gamma$ side chain atoms viewed along $C\alpha$–$C\beta$ illustrate some of the stereochemistry observed.

The structure is essentially the same as that found in parallel crystallographic studies in Oxford; indeed, in 1972, in Peking, we compared in detail our earlier electron density maps, both drawn at a scale of 1 cm to 1 Å. There was actually a moment of acute concern when we put the maps together first and they did not fit—until we realised one was upside down compared with the other. We then saw that there was very good correspondence, if not exact agreement, between them. Correspondingly now, in the insulin dimer, molecule I Peking is molecule II Oxford, and molecule I Oxford is molecule II Peking.

One might not wish, in all cases, to see complete duplication of the X-ray analysis of a protein molecule—so much work is involved. But there are great gains in the present case from having two views of the insulin crystal structure. First, insulin is such an odd molecule and the situation in the crystal is very curious. The two insulin molecules in the asymmetric unit are very similar to one another, yet appear to differ in conformation in a number of details; it is comforting to see how closely the molecules described in the Chinese papers agree with Oxford findings. Earlier small differences between us are diminishing; it may well be that the final comparison will give us reliable estimates of the errors we must expect in general in placing atoms from X-ray data on proteins. The present Peking map at 1.80 Å resolution is the most accurate map available of the insulin electron density defined by experimental, isomorphous phase angles—and may well remain so. The calculations we are carrying out at Oxford, designed to show the electron density at 1.50 Å resolution, depend on the extension of the phases from 1.9 to 1.5 Å by various computing procedures, some very experimental. The total cross checking of our operations by the Peking analysis when we come to compare atomic coordinates should be very valuable.

Many of the comments made by the Chinese insulin research group on their findings are similar to ones we have made ourselves, but they often add illuminating details and occasionally recognise quite different features—for example, they realised that the dihedral angles of the glycine residues, B8, B20 and B23, were all in the region allowed for D residues. This led directly to experiments by the Shanghai chemists and biochemists who showed that B23 might be replaced by D-alanine in the insulin sequence with only partial loss of biological activity, whereas activity vanishes when B23 is replaced by L-alanine.

The second paper carries a stage further the study of structure–activity relations in the insulin field through direct measurements of the interaction of insulin and insulin analogues with receptor proteins in liver and fat cells. It, too, parallels and extends work in other laboratories.

Soluble receptor protein preparations were made by the method of Cuatrecasas, of fat cells by a new method avoiding collagenase. It was found that despentapeptide insulin had almost the same binding capacity as insulin, while deshexapeptide insulin and the corresponding molecule with B23 replaced by D-alanine had reduced, but definite, binding capacity. The results strengthen the view that the non-polar residues of the B chain surface, B12, B16, B24 and B25, are important in receptor binding and that the loop B20–B23 and perhaps also the salt bridge A21–B22 assist in stabilising the conformation in this region. There is a nice discussion in the first paper of the part that conformational variability may play in assisting membrane binding in this part of the insulin molecule.

It will be splendid if we can some day soon all meet and talk over the very interesting observations that are accumulating, East and West, on the structure and function of insulin.

Revising the Cainozoic polarity record

from D. H. Tarling

Now that the main plate tectonic band wagon has passed, the dust can be brushed off the marine magnetic anomalies that were so effective in getting it rolling. It is now possible to examine in more detail the record they provide of past geomagnetic changes and to refine the time scale of polarity changes.

The polarity time scale of Heirtzler *et al.* (*J. geophys. Res.*, **73**, 2119; 1968), based on anomalies recorded on profile V-20 SA in the South Atlantic, has stood up remarkably well. Profile V-20 SA was chosen as the longest available with no marked evidence of changes in the rate or direction of spreading, and the anomalies were dated by assuming that the observed spreading rate at the ridge axis—1.9 cm yr^{-1}—had remained unchanged for the past

80 Myr. The fact that modifications are only now becoming essential is remarkable, and the choice was, to say the least, inspired.

The first evidence of inaccuracies began to appear in 1971, as a result of discrepancies between the ages of fossil-dated sediments lying over igneous rocks which carried the magnetic anomalies and of observed differences of curvature on fracture zones in the South Atlantic (Le Pichon and Hayes, *J. geophys. Res.*, **76**, 6283; 1971), which indicated two-stage spreading (see Mascle and Sibuet, *Nature*, **252**, 464; 1974). At that time the evidence was taken mainly to confirm the available scale, as the differences were generally less than 5%, which were insignificant for the analyses then being carried out.

Since then, however, detailed studies of the anomaly patterns on fast spreading ridges, such as those described by Rea and Blakely on page 126 of this issue, combined with the polarity record in deep-sea sediments, such as that reviewed by Opdyke (*Rev. Geophys. Space Phys.*, **10**, 213; 1972), have provided a generally acceptable revision of polarity scales for the past 22 Myr. The older parts of the scale, however, are not so amenable to checking. Palaeontological dating of sediments lying immediately over igneous rocks which carry the anomaly pattern are uncertain because of the lack of precision in the radiometric dating of stratigraphic zonations of the Tertiary. This arises because most available dates are based on measurements of potassium and argon isotope ratios in glauconites within stratigraphically dated sediments. During the burial of sediments glauconite grows from illite, a mineral which often contains appreciable amounts of relic argon; and further burial may also be responsible for later loss of argon from the glauconite. Furthermore, most deep-sea drilling stopped on encountering the first igneous rocks, some of which are intrusive and therefore post-date the sediments and others of which could be more extensive, isolated flows that may have flowed out over the sedimentary deposits of a few million years. Nonetheless, on such studies, Sclater *et al.* (*Initial Reports of the Deep Sea Drilling Project*, **22**, 381; 1974) have suggested modifications to the ages of certain anomalies; in particular, anomaly 24, which is 60 Myr old on the original scale of Heirtzler *et al.*, is tentatively redated at 56.5 Myr.

Anomaly 24, the oldest found in the North Atlantic between Greenland and Europe, is one of the most critical anomalies (Vogt and Avery, *J. geophys. Res.*, **79**, 363; 1974). On the previous time scale, anomaly 24 predates the first eruptions of flood basalts in Greenland, the Faeroes and Britain, yet it seems reasonable to assume that such flood basalts would be released during tensional rifting immediately preceding continental separation, rather than after the separation has occurred. Molnar and Francheteau, on page 128 of this isssue, suggest one explanation for this discrepancy.

It is possible, they reason, that anomaly 24 is younger than previously believed and that similar arguments hold for the age of anomaly 32. Molnar and Francheteau are careful no to suggest a possible age for these anomalies because of the difficulties involved in obtaining precise radiometri ages for the flood basalts; the polaritie of these basalts indicate eruptions ove periods of less than 2 Myr, but th range of possible radiometric ages i large because of the presence of exces argon in some areas and the occurrence of argon loss in others. But careful segregations of the more reliabl radiometric ages, and the newly available palaeontological evidence for th ages of sediments associated with floo basalts in eastern Greenland (Soper *e al.*, *J. geol. Soc. Lond.*; in the press indicate a probable age for anomaly 24 of either ~~52 or~~ 55 Myr, depending on the accepted radiometric age of the Thanetian Stage (compare 52.5 My by Tarling, *Principles and Applications of Palaeomagnetism*, Chapma and Hall; 1971) on the basis of preliminary palaeontological dates fro deep-sea drill cores. This new evidenc now means that it should be possibl to produce a revised Cainozoic polarit time scale.

Such a revision will necessaril mean recalculation of the frequenc and duration of polarity changes re-evaluation of correlations between eustatic changes and rates of seafloo spreading, re-examination of the history of the breakup of the North Atlantic and other oceans, and so forth but the fact that age discrepancies o some 5% are now becoming so important really reflects the coming-of-age o seafloor spreading as an extremel precise technique.

Hepatitis vaccine: a note of caution

from Arie J. Zuckerman

Viral hepatitis type B is distributed worldwide and there is a particular need for a vaccine for groups which are at an increased risk of acquiring this infection. High risk groups include surgeons, physicians, dentists, nurses, laboratory workers and other health care personnel, haemodialysis patients and their attendants (*Nature*, **235**, 130; 1972), children of mothers who become infected during pregnancy (*Nature*, **249**, 105; 1974), drug addicts, patients and others residing in large institutions, and persons living in certain tropical areas where sanitation is poor. There is also the view, not shared by many, that military personnel should be immunised against hepatitis B.

The repeated failure to passage serially hepatitis B virus in tissue culture has hampered progress towards the development of a safe and effective vaccine. Attention has, therefore, been directed towards the use of other preparations for active immunisation against hepatitis B (*Nature*, **233**, 92; 1971). A known infective serum that contains hepatitis B virus was inactivated by heat and used as the immunogen by Krugman and associates (*J. infect. Dis.*, **122**, 432; 1970; *J. Am. med. Ass.*, **217**, 41; 1971; *New Engl. J. Med.*, **290**, 1331; 1974). The serum treated in this manner was not infective and it successfully prevented or modified hepatitis B in 69% of susceptible persons inoculated with the heated serum and challenged with the infective serum 4–8 months later. Diluted and heat-treated serum may be regarded as an 'inactivated vaccine' but it is a crude way of inducing immunity and it is unlikely to be accepted for general use. This work, however, laid the foundations for unconventional immunogens that could be used as vaccines, and indeed 200,000 doses of one such preparation are now available for preliminary trials in man.

Coat protein

Isolated viral coat protein challenges the body's immune mechanism in the same way as the whole infectious agent and the possibility of using purified spherical 20 nm hepatitis B surface antigen particles, which are free of detectable nucleic acid, seems attractive. Such experimental immunogens have been prepared and a limited number of susceptible chimpanzees have been inoculated with encouraging results. But a variable amount of host protein, and perhaps carbohydrate, may be complexed with hepatitis B viral protein in quantities apparently greater than those in most recognised viruses (Zuckerman and Howard, *Nature*, **246**, 445; 1973). These host proteins may include various pre-existing structures of the liver cell and may thus induce undesirable immunological reactions. Recently, it was reported that antigenic determinants related to human plasma proteins are constituents of hepatitis B surface antigen (Neurath *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2663; 1974). These determinants are apparently related to antigenic specificities on prealbumin, albumin, apolipoproteins C and D, and the gamma chain of immunoglobulin G. Other studies indicated that the larger polypeptides of purified surface antigen are probably adsorbed serum proteins which are necessary for the preservation of antigenic activity.

Host antigens

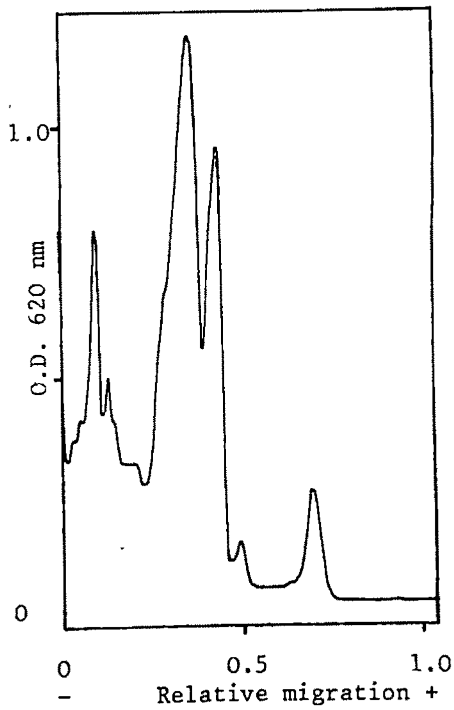
Demonstrable and significant levels of carbohydrate in purified fractions of the antigen have also been reported (Burrell *et al.*, *Nature new Biol.*, **243**, 260; 1973). The total carbohydrate content of purified 20–25 nm antigen particles is reported as 3.6 to 6.5%. Three glycoproteins were found as well as a glycolipid and three major phospholipids (Chairez *et al.*, *Intervirology*, **1**, 224; 1973 and **3**, 129; 1974; Steiner *et al.*, *J. Virol.*, **14**, 572; 1974). The carbohydrate may be necessary for maintaining the structure and functional integrity of the antigenic determinants or the carbohydrate itself may constitute a major antigenic determinant. The carbohydrate might have a novel haptenic specificity which is either virus-coded or virus-induced host cell-coded. Alternatively, the carbohydrate, and some lipoprotein components, might simply be derived from the host cell membranes as the mature virus particles are released. There may be some similarity between such a carbohydrate hapten, or the lipoprotein components, and those carbohydrate and lipoprotein antigens of normal cell surfaces, leading to a degree of tolerance because of a close antigen resemblance between hepatitis B surface antigen and 'self' antigens or alternatively initiating an autoimmune reaction.

Such an autoimmune reaction might be induced by hepatitis B infection because of a change in antigenicity of the hepatocyte cell membranes, due to alteration of existing antigens or the appearance of viral determinants. T lymphocytes responsive to such new antigen determinants could promote a B cell response to unaltered self antigens. The synthesis and release of the resulting autoantibody is subject in turn to control by suppressor T cells.

Liver-specific lipoprotein is a macrolipoprotein which is thought to be a normal constituent of the hepatocyte plasma membrane (Hopf *et al.*, *J. clin. exp Immun.*, **16**, 117; 1974). Williams and colleagues at King's College Hospital and at the London School of Hygiene and Tropical Medicine found evidence of cell-mediated sensitisation to hepatitis B surface antigen in all patients with acute hepatitis B. Transitory sensitisation to liver-specific lipoprotein was detected in many of the patients.

These findings are consistent with the hypothesis that a cell-mediated response to hepatitis B antigen, present early on at the onset of acute hepatitis, is the cause of acute liver damage by a cytotoxic effect on virus-infected cells. If the response to liver-specific lipoprotein persisted, it could be responsible for progression to chronic liver damage. It is also postulated that the progressive liver damage of active chronic hepatitis is due to an autoimmune reaction directed against an hepatocyte surface lipoprotein which is initiated in most cases by infection with hepatitis B virus. This was investigated by Lee and associates (*Br. med. J.*, **1**, 705; 1975) who observed evidence of cell-mediated immunity to hepatitis B surface antigen in 62% of patients with antigen-negative active chronic hepatitis, suggesting a high frequency of previous infection with hepatitis B virus. A cellular response to the antigen was found in the majority of hepatitis B antigen-positive patients. Evidence of sensitisation to liver-specific lipoprotein was found in more than half of the patients, with a similar frequency in the two groups. These results are consistent with the hypothesis that infection with hepatitis B virus is important in initiating the disease in many cases of active chronic hepatitis and that sensitisation to the liver cell membrane antigen is responsible for the perpetuation of the liver injury. Thomson *et al.* (*Nature*, **252**, 721; 1974) demonstrated the killing of isolated rabbit hepatocytes *in vitro* when incubated with lymphocytes from 20 out of 22 patients with untreated active chronic hepatitis. Blocking experiments strongly suggest that the cytotoxicity is due to an immunological reaction directed at a cell surface antigen.

All these observations indicate that immunological mechanisms and the presence of antibodies reacting with various tissue components may well be involved in the pathogenesis of liver damage. It may therefore be undesirable to employ preparations of hepatitis B surface antigen which contain host cell components for immunisation against this infection.



Profile of the polypeptides of purified hepatitis B surface antigen after SDS-polyacrylamide gel electrophoresis. The separated polypeptides were stained with Coomassie Brilliant Blue.

Subunits of the antigen, in the form of small polypeptides, on the other hand, offer an attractive proposition as immunogens. Such preparations would exclude genes of viral and cellular origin and could not be infectious. Several laboratories are investigating now the subunit structure of purified hepatitis B surface antigen by polyacrylamide gel electrophoresis and it has been shown that such subunits consist of polypeptides. It seems that the antigen contains between five and nine polypeptides ranging in molecular weight from approximately 15,000 to 120,000 (see figure). Work is currently in progress to determine if such preparations can be used as vaccines.

The primary sequence of the haptenic peptide of the surface antigen may also provide an approach for the development of a synthetic peptide, which when coupled to a macromolecular carrier could serve as a suitable immunogen. Once detailed data are available on the peptide and amino-acid composition of the antigen, it should be possible to define by animal immunisation the moiety responsible for the antigenic activity.

Immunisation against hepatitis B is now within reach but careful evaluation of the preparations in appropriate non-human primates is essential before small trials are undertaken in human subjects. These studies should be directed not only at the protective efficacy of such immunogens but they should include careful assessment of all their effects on the immune system. ☐

Actin and myosin in non-muscle cells

Secretion, motility and cell division

from Robert S. Adelstein

PROTEINS similar in molecular structure and biological properties to the muscle proteins actin and myosin have been identified in a large number of cells found in both vertebrates and invertebrates. Actin purified from non-muscle cells has the same monomeric molecular weight as skeletal muscle actin (42,000 daltons), contains a single residue of the unusual amino acid N^{τ}-methyl histidine and polymerises into filaments upon alteration of the ionic strength. The details of this polymerisation are not understood but it is thought that actin in non-muscle cells undergoes reversible polymerisation-depolymerisations unlike actin in muscle cells, which is thought to exist only as a filament.

Myosin from vertebrate non-muscle cells resembles muscle myosin (molecular weight 460,000) in being composed of heavy chains (200,000 daltons) and light chains (20,000 and 16,000 daltons in the case of fibroblasts, platelets and macrophages). Similar to muscle myosin, cytoplasmic myosin possesses an enzymic activity which catalyses the hydrolysis of ATP into ADP and inorganic phosphate. This ATPase activity is markedly enhanced at low ionic strength in the presence of Mg^{2+} by the addition of actin. It is noteworthy that cytoplasmic myosin interacts with muscle actin and *vice versa*.

Two major problems occupy the ever expanding number of workers attracted to this field: (1) the location of actin and myosin in non-muscle cells and (2) the function of these proteins (see also *Nature*, **253**; 399; 1975).

Three important cell processes have been postulated to involve cytoplasmic actin and myosin: secretion, cell division, and cell motility. It is important to note that all the evidence presented to date is at best circumstantial, in that no direct evidence for the role of actin and myosin in any of these processes has been reported.

In a recent article Burridge and Phillips (*Nature*, **254**, 526; 1975) presented evidence for the association of actin with the secretory granules of the adrenal medulla. These granules contain neurotransmitters which are released, following exocytosis into the blood stream. The authors succeeded in preparing membranes from partially lysed chromaffin granules which bound rabbit skeletal muscle actin (and very small quantities of chicken smooth muscle myosin). Binding was indicated by finding the contractile proteins and lysed membranes in the same fraction following sedimentation in a sucrose gradient.

The authors supplemented these studies with electron micrographs showing lysed chromaffin granule membranes associated with rabbit skeletal muscle actin filaments (the original photographs being superior in quality to those reproduced in *Nature*). In muscle cells actin is uniquely attached to a Z-line so that 'decoration' of the actin filament with a fragment of myosin, heavy meromyosin, leads to the formation of polarised 'arrowheads' pointing away from the Z-line attachment site. Unfortunately this uniform polarity is lacking in the preparation of membranes and actin filaments examined by these authors raising the possibility that at least some of the filaments might not be uniquely attached to the membrane.

Puszkin and Kochwa in a preliminary communication (*J. biol. Chem.*, **249**, 7711; 1974) presented data suggesting that contractile proteins are important in the release of neurotransmitters from brain tissue. They isolated a complex of actin and 'relaxing proteins' from rat brain synaptosomal membranes. The actin–'relaxing proteins' complex interacted with synaptic vesicles from brain, preloaded with ^{14}C glutamate and presumably containing brain myosin. The results of the interaction (in the presence of Ca^{2+}) were release of the labelled glutamate and activation of the Mg-ATPase activity of the myosin. The work is incomplete in that neither the relaxing proteins (presumably troponin) nor the myosin were positively identified. Moreover the release of ^{14}C-glutamate is assumed to correlate with the secretion of neurotransmitter.

Evidence that actin in HeLa cells (human tumour cells grown in tissue culture) might play a part during one phase of cell division was first proferred by Schroeder (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 1688; 1973) who identified actin in the contractile ring of these cells. The identification was made by treating the cells with glycerine so they would be permeable to heavy meromyosin which interacted with actin filaments to form the unique arrowhead pattern alluded to above. Again, the evidence is circumstantial. The presence of actin implies, but does not prove, that it is functioning (perhaps with myosin?) to cleave the cells.

A role for actin in cell motility and phagocytosis was suggested by Boxer *et al.* (*New Engl. J. Med.*, **291**, 1093; 1974) who investigated polymorphonuclear leukocytes isolated from a patient suffering multiple infections. These cells failed to migrate normally an ingested particles at a slower rate than controls. Actin isolated from these cells could not polymerise to the same extent as actin from the white cells of normal controls. It must be stressed that only a single patient's cells were examined and that the process of actin polymerisation using non-muscle actin is not well understood at present. But the principle of using a cell showing a defect in its motile behaviour as a source for studying actin is important.

Future experiments in this field should be directed at: (1) complete characterisation of the various proteins and their interaction; (2) the *in situ* identification of the contractile proteins using antibodies that have been shown to be specific for either actin or myosin by a number of rigorous criteria; (3) the removal of a specific link (for example, Ca^{2+} ATP, troponin) in the contractile mechanism which results in changes that can be related to cell function; (4) further studies looking for specific defects in the contractile proteins of abnormally functioning cells; (5) identification of a specific inhibitor of actin–myosin interaction which can be used *in vivo* (as well as *in vitro*) to study changes in cell function. The list, of course, can be ex

A hundred years ago

Curious Phenomenon of Light

ROWING on Loch Lomond recently, above Luss, there were seen to the north-west, at an apparent distance of about 100 yards, two bright lines of prismatic light, 60° apart and on the level of the water. Their length seemed to equal the breadth of a rainbow. Their violet ends were towards each other, and were joined by a line of dull white light, to the middle of which the sun and the spectator were at right angles. Standing in the boat, the colour and brilliancy were lost, and only a diffuse white light was visible. The time was 10 A.M. The sun was hot, the sky cloudless, the air hazy and still, and the loch a mirror. This apparition fled before our approach for some minutes, till dispelled by a slight breeze, which rippled the water.

Luss WM. M'LAURIN

from *Nature*, **12**, 26; May 13, 1875

panded but perhaps in the near future we shall have direct evidence as to the exact role of cytoplasmic actin and myosin.

Cell movement

from Robert Shields

SINCE the discovery that non-muscle cells contain actin it has become almost an article of faith among cell biologists that cell movements are somehow generated by actin–myosin interactions. Unfortunately non-muscle cells do not present their actin–myosin complexes in the nicely structured array seen in striated muscle and although microfilaments have been shown to contain actin-like proteins quite how this was translated into cell movement has been obscure until recently.

Cellular locomotion is most conveniently followed in tissue culture where it has been clear for some time that only limited areas of the underside of the cell approach closely to the surface of the culture vessel. Electron microscopy of a section of a cell's leading lamella reveals that electron dense plaques form on the inside of the cell membrane where the cell comes closest to and probably adheres to the culture vessel. These points can be seen in scanning electron micrographs just behind the ruffling cell membrane (Revel *et al.*, *Expl Cell Res.*, **84**, 207; 1974).

Soon after the formation of the plaques bundles of microfilaments can be detected running obliquely from the plaques towards the rear of the cell (Abercrombie *et al.*, *Expl Cell Res.*, **67**, 359; 1971). This arrangement of adhesion plaques near the cell borders and microfilament bundles running from the plaque parallel to the long axis of the cell has been beautifully confirmed in scanning electron microscope studies of the replicas of the undersides of untransformed BHK cells (Revel and Wolken, *Expl Cell Res.*, **78**, 1; 1973).

Because of the abundance of these points of adhesion near the advancing edges of cells it was natural to assume that cell locomotion might result from pulling of the microfilament bundles on the points of adhesion to the substratum. Evidence to support this idea has recently emerged in a series of papers from a group at Cold Spring Harbor. What these workers did was to raise antibodies to purified actin or purified myosin (which is no mean feat) and use indirect immunofluorescence to detect binding of actin or myosin antibodies to fixed cells by fluorescence microscopy. Untransformed 3T3 cells showed bright staining with actin antibody along microfilament bundles which seemed to be close to the underside of the cell and orientated away from the cell periphery (Goldman *et al*, *Expl Cell Res.*, **90**, 333; 1975). Similar patterns of staining were seen with anti-myosin antibody and in addition both antibodies stained the cytoplasm diffusely.

The intense patterns of staining along the microfilament bundles and the diffuse pattern over the body of the cell probably correspond to the two extreme arrangements of microfilaments encountered: bundles and a three-dimensional matrix that underlies much of the cell surface. The experiments strongly suggest that the bundles of microfilaments attached to the adhesion plaques contain both actin and myosin-like proteins and that the attachment of these bundles of filaments to the adhesion plaques could provide a mechanism for cellular locomotion.

Examination of cell replicas by scanning electron microscopy revealed another interesting feature. The underside of BHK cells transformed with polyoma virus showed few bundles of microfilaments or obvious points of cell substratum attachment, whereas such features were frequent in untransformed BHK cells (Revel and Wolken, *ibid*). Recent cell fractionation studies have also suggested that virally transformed cells have less actin associated with their cell membrane than do their normal counterparts (Wickus *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 746; 1975). A series of indirect immunofluorescence experiments using actin antibody and rat embryo cells transformed with a newly isolated temperature sensitive mutant of SV40 virus showed what was happening. At the permissive temperature (where the cell exhibits its transformed phenotype) the brightly staining actin-containing bundles of microfilaments are almost completely absent but the diffuse pattern of cytoplasmic staining remains; however, after cultivation at the non-permissive temperature (where the normal cell phenotype is re-expressed) bundles of microfilaments, which stain with actin antibody, appear (Pollack *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 994; 1975). From these results it would seem that transformed cells may have some defect in their ability to organise microfilament bundles and adhesion plaques and this may account for their altered cell–substratum adhesion and altered locomotion. ☐

Isotope clue to end of glaciation

by John Gribbin

THE use of measurements of oxygen isotope ratios to provide a clue to past temperatures is now a familiar tool of climatologists. But Kenneth and Shackleton have given a new twist to the technique in a study reported in *Science* (**188**, 147; 1975). They interpret a large change in the isotope pattern in planktonic foraminferans from Gulf of Mexico sediments as arising from the influx of fresh water from the melting ice sheet at the end of the Wisconsin.

This certainly seems more plausible than trying to explain that particular feature in terms of a temperature change, since it would require an increase of 8 °C to 33 °C at a time (between 15,000 and 12,000 years ago) when, judging by other evidence, the Earth was not in a warm phase. The change in salinity caused by the influx of fresh water to the gulf would produce the same effect (if surface salinity fell by 10%), and the argument is strengthened by a comparison of shells of deep-water creatures with those that lived near the surface; the isotope ratios in the latter show five times the change found in the former.

The model also fits in well with present understanding of the geography of the ice sheet, which would have prevented a substantial easterly flow of meltwater until about 12,000 years ago, when the Hudson River system opened up; before that time, the chief escape route for meltwater would have been a southward flow through the Mississippi River system.

All this tells us little new about recent glaciation. The real interest, of course, is a possible technique for investigating the extent of earlier ice sheets. As Kennett and Shackleton summarise the work, "earlier phases almost certainly would have influenced salinities in the Gulf of Mexico and will provide information on the extent of earlier ice sheets, since it can be assumed that no substantial meltwaters would have entered the Gulf unless the southward extent of the ice sheet was greater than the latest Wisconsin limit about 11,200 years ago. Such an approach will be of particular value since little is known about earlier episodes of deglaciation, because succeeding glacial advances have redistributed the older deposits".

Carbon dioxide fluctuations

from Peter D. Moore

THE global movement of carbon between non-living and living matter is one of the many cyclic processes upon which man's industrial activities are having considerable effect. The combustion of fossil fuels accelerates one part of the 'natural' cycling of carbon; it replaces the respiratory activity of decomposer organisms, whose consumptive processes were impaired by anaerobic conditions during the accumulation of the organic detritus which is now coal, oil and gas. Industrial combustion, however, is almost certainly responsible for the observed rise in ambient atmospheric carbon dioxide levels over the past sixteen years in Hawaii. Baxter and Walton (*Proc. R. Soc.*, **A318**, 213; 1970) suggest an increase of 22% on pre-industrial levels of atmospheric CO_2. Evidently the increased output of carbon dioxide, resulting from increasing industrialisation, is not being fully compensated by CO_2 consumption in other global reservoirs.

The major potential carbon reservoirs which might be expected to increase consumption of atmospheric CO_2 as concentrations rise are the oceans and the living organic matter of the planet. It is obviously a matter of considerable urgency to develop predictive models of this equilibrating system in order to determine the likely outcome of man's industrial activity; several such models now exist (for example, Fairhall, *Nature*, **245**, 20; 1973; Broecker *et al.* in *Impingement of Man on the Oceans*, edit. by D. W. Hood; Wiley, 1971). Opinions differ as to the likely influence of the additional carbon load upon the chemistry of ocean water (see Whitfield, *Nature*, **247**, 523; 1974).

World biomass variations are not easily estimated. One might predict increases in photosynthetic production as a consequence of enhanced CO_2 levels, but one must set against this the possibilities of reduced productivity because of raised SO_2 and O_3 concentrations in the atmosphere of industrial countries and also the destruction by man of many naturally productive areas. The production : respiration ratio of the world's biota could be moving in either direction. Reiners (and several other contributors to *Brookhaven Symp. Biol.*, **25**; 1973) have drawn attention to the general lack of reliable data and the wide disparity among estimates of such carbon reservoirs as living biomass and detritus pools, let alone transfer rates. Attempts have also been made to use tree growth rings as indices of forest production (for example, Whittaker *et al.*, *Ecol. Monogr.*, **44**, 233; 1974) and Farmer and Baxter (*Nature*, **247**, 273; 1974) have used the isotope ratio of $^{14}C/^{12}C$ in efforts to identify the contribution of fossil carbon to the growth rings of trees in Britain.

In this issue of *Nature* (page 136) Hall, Ekdahl and Wartenburg use a method which has been applied in many smaller scale studies to estimate trends in the biotic metabolism of carbon in the Northern Hemisphere. Their idea is based upon the flux study concept as used for the determination of forest respiration by Woodwell and Dykeman (*Science*, **154**, 1031; 1966), but rather than diurnal changes, they use seasonal fluctuation in ambient CO_2 levels (values are corrected by subtraction of the estimated residuum of industrially derived CO_2 after partition with the oceans). Increasing CO_2 levels in autumn and winter provide a measure of the respiration of the hemispheric ecosystem and decreasing levels in spring and summer give a measure of net photosynthesis. Using the data from the Mauna Loa observatory, Hawaii, they calculate hemispheric net production and respiration for the sixteen years over which data are available and they find no significant change during this period. This suggests that either the total biomass of the hemisphere is unchanged, or any loss of productivity due to pollution or changing land use has been compensated by an increase in the productivity of the remainder. It is possible to argue about the best figures to use for industrial carbon output and the equilibration of this carbon with the oceans (the prime considerations in the adjustment of the Mauna Loa data) but the authors claim that the outcome of their calculations is relatively insensitive to possible errors in these data. Their plea for a more extensive worldwide monitoring of atmospheric CO_2 fluctuations as an aid, among other things, to the detection of any major variation in global carbon metabolism, should be supported by anyone with a sense of responsibility for the environment.

Statistics and climatic change

from Michael Kelly

GREAT advances are currently being made in the study of climatic change. This progress is attributable not only to greater academic and, in certain countries, governmental interest in the subject but also to the increasing use of powerful statistical tools in the analysis of climatic time series.

Post-glacial climatic change can be viewed as movement between atmospheric circulation states of predominantly strong, westerly airflow (leading to warming of higher latitudes in the sector or sectors affected, as occurred globally in the first half of the twentieth century) and those of predominantly weaker, more meridional airflow (leading to cooling). Characteristic time scales or periodicities can often be attached to variations in climate; this had led to many attempts to explain the observed persistence of a particular circulation state for periods of months to centuries and also the change to a different state at fairly regular intervals Climatic cycles may eventually prove of great value in climatic forecasting but until a physical reason for their continued existence is established, such forecasts can only be tentative.

The search for the causes of climatic change and climatic cycles is proceeding on two fronts: computer modelling of the atmospheric circulation and statistical analysis of climatic data. The potential of both of these approaches is great but, at present, most computer models are too coarse to differentiate between different circulation states experienced during the last millennia and it is the second, more traditional approach to the study of climatic change that has been greatly improved by the availability of new statistica methods and that is rapidly increasing understanding of climatic change.

A recent paper by Trenberth (*Q. J R. met. Soc.*, **101**, 55; 1975) illustrates the use of sophisticated data analysis in a study of ocean–atmosphere interaction in the region of New Zealand and Australia. Empirical orthogona function analysis was used to identify the major sea level pressure (SLP) anomaly patterns, that is, atmospheric circulation states, and the major sea surface temperature (SST) anomaly patterns for the period 1959–1972 Spectral and cross-spectral analysis o time series of the pattern coefficients then revealed relationships, both current and lag, between the SLP and SST anomaly patterns, associated with a quasi-biennial periodicity which ha been observed in many climatic parameters. These relationships enabled Trenberth to construct a sequence o SLP and SST anomaly charts for the two-year cycle, which showed that the SST anomalies were largely caused by oceanic advection resulting from the wind drag associated with the differen SLP patterns.

This research did not indicate tha feedback from ocean to atmosphere was of great importance in the region studied. But work in other areas, particularly the Pacific and North Atlantic has shown that anomalous sea temperature patterns often reinforce the atmosphere circulation states that produce them Although this positive feedback can explain the persistence o certain atmospheric circulation states it cannot explain the observed regularity of many climatic cycles. If this is to be explained in terms of ocean–atmosphere interaction, some form of complex negative feedback between ocean and atmosphere must be postulated.

Complete nuclear isobaric quintet

from P. E. Hodgson

IF nuclei of the same mass (isobars) are grouped together, it is found that their states can be conveniently classified using the isobaric spin vector **T**, analogous mathematically to ordinary spin. States of the same structure in different isobars have identical nuclear quantum numbers, including isobaric spin, and differ only in the third component T_3 of the isobaric spin vector. This quantum number T_3 is directly related to the excess of neutrons over protons, thus $T_3=\frac{1}{2}(N-Z)$.

For example, the ground states of ^{25}Mg (12 protons and 13 neutrons) and ^{25}Al (13 protons and 12 neutrons) have the same nuclear structure and $T=\frac{1}{2}$, but the former has $T_3=\frac{1}{2}$ and the latter $T_3=-\frac{1}{2}$. These states constitute an isobaric spin doublet. Some of the higher states of these nuclei have $T=3/2$, and then as before $T_3=\frac{1}{2}$ and $T_3=-\frac{1}{2}$ correspond to states in ^{25}Mg and ^{25}Al of the same structure, and in addition there are states of the same structure to be found in ^{25}Na (with $T_3=3/2$) and ^{25}Si (with $T_3=-3/2$). These four states comprise an isobaric spin quartet. The states of nuclei with an even number of nucleons can be similarly classified into isobaric singlets, triplets, quintets and so on.

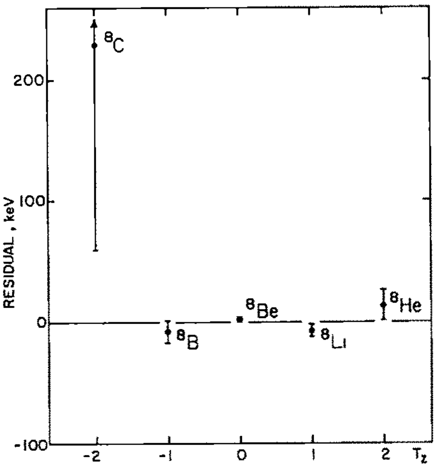
Analysis of the structure of these isobaric spin multiplets, as they are called, showed that for states of pure isobaric spin the mass excesses of nuclei in a particular multiplet are given by the simple quadratic expression

$$\Delta M=a+bT_3+cT_3^2$$

where a, b and c are constants. Multiplets with up to three members automatically satisfy this relation, which is therefore not useful, but higher multiplets provide a means of testing its accuracy. Thus if the masses of all four members of a quartet are known then any three of them determine a, b and c, and from these the mass of the fourth can be calculated and compared with the measured values.

Over the past few years several such quartets have been measured, and on the whole have confirmed the above formula to a high degree of precision with some small systematic discrepancies that can be explained by higher-order effects.

A more severe test of the formula is provided by higher multiplets, but this is difficult experimentally because the members of these multiplets with higher T_3 are usually states of highly unstable nuclei. Recently however a complete set of masses for the quintet in nuclei of mass 8 comprising the lowest $T=2$ states in ^{8}C, ^{8}B, ^{8}Be, ^{8}Li and ^{8}He has been obtained by Robertson and Chien at Michigan State and Goosman at Brookhaven (*Phys. Rev. Lett.*, **34**, 33; 1975) and these have been used to test the isobaric mass formula. If the deviations from the above formula are represented by extra terms dT_3^3, eT_3^4, and so on, then a quartet determines one of these terms and a quintet two.



Amounts by which individual masses exceed those given by a weighted fit of the quadratic isobaric mass equation to the masses of the $A=8$ quintet.

The five masses were first fitted by the above equation with the addition of the dT_3^3 and eT_3^4 terms, and it was found that $d=-18\pm14$ keV, and $e=13\pm7$ keV, indicating that e, but not d, is probably significantly different from zero. The residuals in a three parameter fit to the above formula are plotted in the figure, and the odd–even staggering corresponding to a non-zero value of e is apparent. It is clear that a more accurate value of the mass of ^{8}C is needed, and this would increase the sharpness of the test.

There are several effects that could cause deviations from the simple three-parameter equation. One of these, the isospin mixing of $T=0$ and $T=2$ states in ^{8}Be, is readily calculable, and gives $d=0$ and $e\simeq-1$ keV. This is consistent with the result of a fit to the measured masses when d is set equal to zero. Remaining small differences may be caused by increasing Coulomb repulsion in the neutron-deficient members of the quintet.

The results from the first complete quintet thus confirm the high accuracy of the simple isobaric mass formula, and indicate that the very small deviations can be accounted for by calculable higher order effects.

Does San Miguel threaten San Diego?

from Peter J Smith

THE San Miguel Fault in Baja California (Mexico) strikes roughly parallel to the other major faults in the San Andreas system and, like those other faults, presumably results from the north-westerly movement of the Pacific Plate with respect to the North American Plate. The detailed relationships between the San Miguel Fault and faults further to the north in the United States have not yet been established precisely, however, although Wiegand (*Bull. Ass. engng Geol.*, **7**, 107; 1970) and others have proposed that a shear zone which begins with the San Miguel Fault in the south-east extends right through to the Inglewood fault zone in the north (the site of the Long Beach earthquake of 1933). This suggested shear zone would also include the Rose Canyon fault zone which passes through San Diego and Tijuana.

If these connections are proved, it follows that the behaviour of the San Miguel fault zone is pertinent to the problem of seismic hazard in San Diego; and for this reason Reyes *et al.* (*Geophys. Res. Lett.*, **2**, 56; 1975) have, since 1970, been measuring the microearthquake activity at various sites in the vicinity of the fault. They found that the overall rate of microearthquake activity at the south-eastern end was about 100 events a day (December 1970–December 1973), although some individual rates rose to 600 and many were significantly higher than those observed along most of the San Andreas Fault in southern California. By contrast, the overall activity towards the more critical (for San Diego) north-western end of the San Miguel Fault was about 20 events a day, with individual rates of up to 70 a day.

The San Miguel fault zone is thus microseismically active. But what does it mean in terms of larger, potentially destructive earthquakes? The problem, as Reyes and his colleagues acknowledge, is that microearthquake activity is not necessarily indicative of long term seismic activity. For example, the 1857 Californian earthquake occurred along a section of the San Andreas Fault which is now 'locked' and exhibits very little microseismicity, although in other sections of the fault microearthquake rates are consistent with the seismicity observed over the past few decades. But although precise correlations cannot be made, the activity observed by Reyes *et al.* suggests that the seismic risk to San Diego and Tijuana from the north-western San Miguel fault zone should not be taken too lightly. □

Organ culture

from Michael Balls and Marjorie A. Monnickendam

The British Society for Cell Biology held a symposium on organ culture in biomedical research at the University of East Anglia on 8–11 April, 1975.

IN the opening session, Dame Honor Fell (University of Cambridge) outlined the historical development of organ culture, and stressed that, though some well-meaning organisations were currently advocating the use of organ and cell cultures to replace experiments on live animals, there were insuperable objections to this as a general policy. Although organ culture experiments gave useful information which could not be obtained from animal experiments, there were many factors operating *in vivo* which could not be satisfactorily mimicked *in vitro*.

Giselle Hodges (Imperial Cancer Research Fund, London) reviewed the range of organ culture techniques currently in use, and J. Simnett (University of Newcastle-upon-Tyne) stressed the importance of care in the handling and preparation of tissues while setting up cultures.

The usefulness of organ culture in morphogenetic studies was shown in papers on germinal tissues (R. Dubois, Institut d'Embryologie, Nogent-sur-Marne), the kidney (Y. Croisille, Nogent-sur-Marne), cartilage and bone (Sylvia Fitton Jackson, Strangeways Laboratory, Cambridge), nervous tissue (S. Aparicio, University of Leeds), and skin and its derivatives (P. Sengel, University of Grenoble; A. Melcher, University of Toronto). C. Cruickshank (MRC Skin Unit, Birmingham) reviewed tissue culture studies on cell differentiation and function in adult skin, and W. de Voogd van der Straaten (Rijks Universiteit, Utrecht) discussed the suitability for cell kinetics studies of the exfoliated chick tracheal epithelium *in vitro*.

A number of contributions demonstrated the value of organ culture techniques in endocrinology, and the problems which can arise. Isabel Forsyth and E. Jones (National Institute for Research in Dairying, Reading), and R. Dils (University of Nottingham) discussed the hormonal induction of milk fat synthesis and changes in enzyme activities and nucleic acid synthesis in cultured mammary glands. Margaret Ryle (Birmingham and Midlands Hospital for Women) outlined work on endocrine aspects of the ovary, comparing the results of short-term incubation and long-term culture, and drawing attention to the problems which arise because of the need to support the tissue and the use of sera in media. *In vitro* investigations on the developing and adult pars intermedia were described by P. Chatterjee (St Mary's Hospital Medical School, London), and Ilse Lasnitzki (Strangeways Laboratory) and D. Cannon (St Helier Hospital, Carshalton) discussed hormone effects and hormone metabolism in the prostate gland. The pig costal method for quantifying the activity of serum somatomedin (the active intermediary of growth hormone) was described by J. Williams (Institute of Child Health, London). Studies on the foetal rat pancreas concerned the control of insulin synthesis and release by islet beta cells in organ culture and in monolayer cell culture (A. Lambert, University of Louvain) and amylase production by acinar tissue maintained in chemically defined medium in circumfusion organ culture (L. Murrell, University of Tennessee).

J. Reynolds (Strangeways Laboratory) opened a more clinically oriented session with a discussion of *in vitro* methods for studying the role of hormones and vitamins in bone resorption. G. Easty (Institute for Cancer Research, London) then discussed the production of osteolytic substances by tumours. In a fascinating talk, he related *in vitro* and *in vivo* observations, showing that the release of osteolytic activity (due to prostaglandins and a high molecular weight component) by human breast tumours *in vitro* was inhibited by high doses of aspirin, and that, in an animal tumour model, bone lysis and hypercalcaemia (though not tumour growth) were inhibited by aspirin and related drugs. Etienne Wolff (Collège de France, Nogent-sur-Marne) described the methods he pioneered for the long-term maintenance of human tumours *in vitro*, and reviewed the results of investigations on tumour growth, growth inhibition, and the effects of ionising radiations. Dorothy Easty (Institute for Cancer Research) tackled the problem of quantifying tumour invasiveness by examining the ability of suspensions of tumour cells to penetrate various tubular and membranous tissues, and measuring the effects of various drugs on invasiveness. Elizabeth Defries (Imperial Cancer Research Fund) reviewed chemical carcinogenesis in organ culture, where the major problem is to determine the extent to which morphological changes *in vitro* are related to the ability of the tissues to form tumours *in vivo*. J. Masters (The Royal Infirmary, Edinburgh) critically reviewed an *in vitro* method for predicting the hormone sensitivity of human breast tumours. His cautious approach was backed up by J. Dickson (University of Newcastle-upon-Tyne), who pointed out that, although *in vitro* biochemical responses of human tumours to drugs and/or hyperthermia indicate the existence of sensitive populations of cells within tumours, because of the complexities of the host–tumour relationship, one could not assume that treatment effective on a tumour *in vitro* would be effective *in vivo*.

The effects of external agents on cultured tissues were described by several speakers. Sylvia Reed (MRC Common Cold Unit, Salisbury) discussed the growth of viruses and mycoplasmas in organ culture. The technique has proved helpful in a number of ways; for isolating and growing viruses which would not grow in permanent cell lines, for examining the role of local immunity by comparing virus growth in tissues from immune and non-immune animals, and for examining interactions between viruses and mycoplasmas in mixed infections. There was no correlation between the virulence of viruses *in vivo* and their cytopathic effects *in vitro*. Lynne Reid (Cardiothoracic Institute, London) discussed the synthesis and secretion of glycoproteins by human bronchial submucosal glands, comparing normal and hypertrophied glands, and considering the effects of various drugs on them. T. Rae (Strangeways Laboratory) described a method for using rat foetal knee joints in culture as a means of measuring the tolerance of tissues towards materials used for orthopaedic implants. D. Lucas (University of Manchester) reviewed work on the effects of X-irradiation on embryonic, normal adult, and neoplastic tissues.

Although most of the discussion in the symposium was concerned with mammalian and human tissues, the host institution contributed three papers which illustrated the potential value of long-term organ cultures of amphibian tissues. These were concerned with the control of renin production and release (R. Worley), activation and blockade of hepatic adrenoceptors (D. Brown), and the hepatotoxic effects of high concentrations of paracetamol (S. Gater).

Concluding the proceedings, L. Franks (Imperial Cancer Research Fund) said that this should be the last symposium concerned with organ culture methods, for, like electron microscopy, the technique had now come of age: organ culture should now be regarded as a standard method which could be applied to most biological problems. He concluded that this was largely due to Dame Honor's unfailing ability to give good advice, and to her success in passing on her belief in the importance of a critical appraisal of an apparently ordinary object looked at from an extraordinary angle.

review article

Sex control in silkworms

Vladimir Strunnikov*

The production of hybrid silkworms yielding a very high proportion of male larvae is of great importance to the silk industry, because of the very much higher yield of silk from males. Strains giving as many as 98% male offspring have now been developed from mutants with translocations of the X chromosome.

THE problem of sex control in the silkworm *Bombyx* is one of great practical and theoretical importance. Male silkworms are more viable and produce more silk than do females. The commercial breeding of exclusively male silkworms would mean producing 15–18% more silk than is now obtained from bisexual strains. Furthermore, the use of sex control methods would solve the technically complex problem of preparing interbreed hybrids, since there would be no need for the present labour-intensive and inaccurate methods of separation of females and males.

Female silkworms are heterogametic (XY) and the males homogametic (XX). (The X and Y chromosomes of lepidoptera are often known as Z and W respectively.)

A variety of environmental agents, irradiation and thermal shock for example, disturb the normal processes of germ cell maturation and fertilisation and form the basis for the experimental control of sex in silkworms. In this article I will review the application of 'chromosomal engineering' for the production of unisexual and 'autosexing' strains of *Bombyx mori.* Four techniques will be considered, two of which are already of commercial interest.

Artificial parthenogenesis

Artificial parthenogenesis was discovered in silkworms by Tikhomirov in 1886. In his experiments, as in those of many other investigators, parthenogenetic eggs developed abnormally, and only in rare cases hatched into larvae.

In 1940 Astaurov[1] developed a simple and very reliable method for obtaining parthenogenetic offspring. He dissected eggs from the ovarioles and, after ageing for 10–12 h, immersed them in a water bath at 46 °C for 18 min. After this treatment the eggs were kept in water at room temperature for 5–10 min. The activated eggs were then kept at 15–17 °C and 80% r.h. for 3 d, and then under normal conditions.

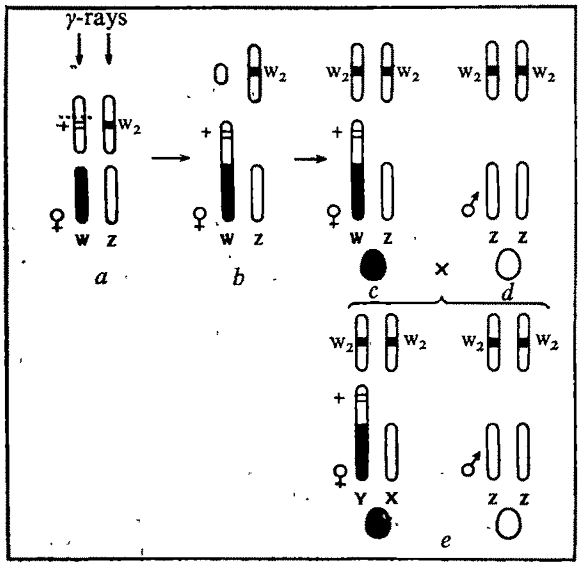
When layed the silkworm egg's nucleus is blocked at metaphase I. Normally fertilisation stimulates both the completion of the reductional first meiotic division and the subsequent equational second division. Heat treatment of unfertilised eggs apparently stimulates these maturation divisions and at the same time destroys the first division spindle.

The second meiotic division is normal and diploid pronuclei are formed. These pronuclei are all XY and hence all parthenogenetic individuals are female and identical in genotype to their mother. By selection Astaurov[2] has produced strains from which 95% of eggs will develop, after activation, by ameiotic parthenogenesis. About 98% of the larvae develop into adult moths—a survival rate better than that of most bisexual hybrid strains.

Spontaneous parthenogenesis in silkworms ending in hatching is very rare[3,4]. The mechanism of spontaneous parthenogenesis differs from the previously described induced ameiotic parthenogenesis since both meiotic divisions occur normally—diploidy being restored by the fusion of daughter cleavage nuclei. Thus spontaneous parthenogenesis is meiotic. Its frequency can be increased by various agents, such as low temperature (−5 to −17 °C), high temperature (44–50 °C) or exposure to CO_2[5,6]. These treatments also induce meiotic parthenogenesis in 95% of eggs, which reach the stage of the pigmentation of the serose, and only 2–3% of eggs are induced towards ameiotic parthenogenesis. With an increase of exposure doses the eggs are stimulated only towards ameiotic parthenogenesis.

After meiotic parthenogenesis two types of embryo are formed; XX and YY, both being completely homozygous. YY embryos are inviable. Presumably because of homozygosis

Fig. 1 The production and use of Y:10 translocation with w_2^+ for the production of a strain in which all male eggs are white and all female eggs coloured.



---

*Address: Laboratory of the Biology of Reproduction and Sex Control, Institute of Development Biology, Academy of Sciences of the USSR.

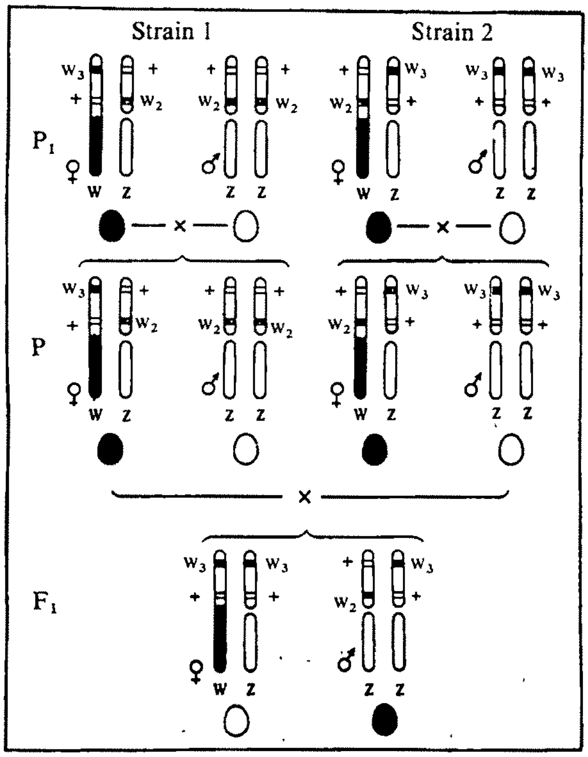


Fig. 2 Construction of two sex-marked strains using the Y:10 translocation and the linked egg colour mutants w$_2$ and w$_3$. Both strain 1 and strain 2 breed true and have coloured female and white male eggs. Their F$_1$ has coloured male and white female eggs.

for lethal or semilethal mutations only 8–9% of XX embryos hatch; they are, of course, all males. Because of the greater viability of these heterozygous females, compared with the homozygous males, the larval sex ratios are usually of the order of 93 males to 7 females.

Thus, depending on the type of activation technique used silkworms which are either entirely females (and heterozygous) or predominantly males (and homozygous) can be produced at will.

Dispermic androgenesis

Dispermic androgenesis in silkworms was discovered independently in Japan by Hasimoto[7] and in the Soviet Union by Astaurov[8]. As a result of heat treatment of eggs one hour after laying (for 1 h at 40 °C)[6] or of X-irradiation of oocytes and heat treatment after insemination (18 min at 46 °C)[8] the maturation divisions are so disturbed that no female pronuclei are formed. Since silkworms are polyspermic the opportunity then arises for two different male pronuclei to fuse and form a diploid zygote nucleus. Since the male silkworm is homogametic all individuals developing by androgenesis are male.

The irradiation of oocytes in the body of a female moth before copulation with the doses of 80–90 krad, after further heating, yielded twice or three times as many androgenous caterpillars as were obtained from non-irradiated but similarly heated eggs. The embryos formed after the fusion of an irradiated female pronucleus with a male pronucleus are unviable. That is why the irradiated oocytes give only androgenous male offsprings[9,10]. The timing of the subsequent heat treatment is critical—it should coincide precisely with prophase of the second division (70 min after laying at 23 °C). Under optimal experimental conditions as many as 20–30% of treated eggs may develop as androgenous males[11].

Double insemination of females by different males allows normally viable androgenous offspring to be produced following fusion of sperm pronuclei from different fathers[12].

Neither parthenogenesis nor dispermic androgenesis is yet a practical technique for producing a single sex in silkworms on a commercial scale. Two techniques that serve the same end and are commercially viable will now be described.

Development of sex-marked breeds

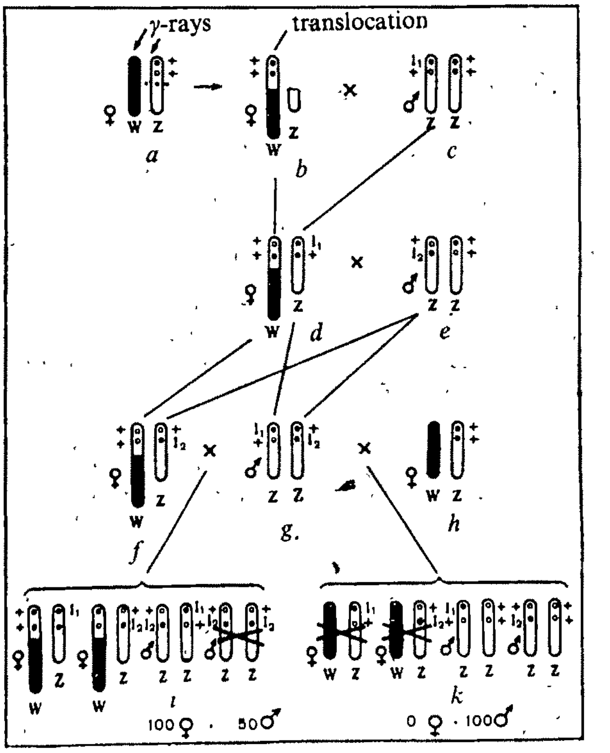
One of the first steps toward evolving methods of sex control on a commercial scale was the development of sex-marked silkworm breeds. At first one such breed, sex-marked in the egg stage, was obtained by Tazima[13] and later two breeds of this kind were evolved in the Soviet Union[14]. Although these breeds have never had a wide distribution in silkworm breeding, the methods used in making them will be described below to make it easier to understand the need for, and the essence of, more complicated methods for obtaining faultless sex-marked breeds.

On chromosome 10 of the silkworm there is a gene, w2, the wild type allele of which determines the formation within the developing embryo of a dark pigment giving the embryos their normal coloration. A recessive mutation at this locus blocks the formation of this serosal pigment and the eggs remain white.

An irradiation induced translocation has transferred the w_2^+ allele onto a Y chromosome (Fig. 1). Strains in which both the chromosomes 10 are structurally normal and the Y chromosome carries the translocation are viable, although somewhat reduced in weight, despite aneuploidy for the region of chromosome 10 distal to the translocation break point. If the chromosomes 10 are both marked with the recessive w$_2$ the translocation females will produce, on crossing to homozygous w$_2$ males, two types of egg—white and coloured—which will develop exclusively into males and females respectively.

Although a practical method for distinguishing male and female embryos, this technique suffers from the fact that the w$_2$ homozygous males have lowered viability. For this reason 'autosexing' strains have been developed which have dark female and white male eggs but which, when crossed, give dark male eggs and white female eggs[15].

Fig. 3 The construction and use of a balanced X-linked lethal stock by the use of an X:Y translocation which covers both lethal loci. The stock is balanced (bottom left) with a 2:1 sex ratio. On outcrossing only male progeny are viable (bottom right). See text.



Aneuploid segregants from the Y:10 translocation that carry the translocated Y:10 element and a single normal chromosome 10 are viable and fertile females. In strain 1 the translocated chromosome is marked with w_2^+ and w_3. w_3 is a recessive mutation also localised at chromosome 10 which also results in white eggs. It fully complements with w_2. The normal chromosome 10 of strain 1 females is marked with w_2 and w_3^+. The males are homozygous for w_2. Strain 2 carries the same translocation but now marked with w_2 and w_3^+ and with its normal chromosomes 10 marked with w_2^+ and w_3. Both strains breed true and have coloured female eggs and white male eggs. Yet when strain 1 females are crossed to strain 2 males all male eggs are wild type and all female eggs are white (Fig. 2).

The advantage of these strains over that previously described can be seen from a consideration of the logistics of silkworm breeding. During the production of pure breeds the females are more important than the males—in these strains the females have coloured eggs and full viability. But for silk production males are more important than females and, in the strain hybrid, it is they that have the wild type egg colour. The translocated females resume their normal weight with the restoration of the balance of the tenth autosomes.

Automatic photoelectric devices can sort out hybrid eggs according to colour, and hence sex, at a rate of 140 eggs^{-1}. This may seem high yet it is inadequate for commercial breeding which requires the separation of tens of billions of eggs. This method is only used for the preparation of hybrid stock, hybrid males for commercial breeding being isolated by a different genetic method.

Use of balanced sex-linked lethals

X-linked lethals have been used in two ways to produce offspring that are entirely male. Males heterozygous for an X-linked lethal give 2:1 male:female sex ratios when crossed to females. Males heterozygous for two different sex-linked lethals, will give no viable female progeny. The construction of such stocks is normally impossible but can be done, in silkworms, by either dispermic androgenesis or by the use of duplications of some regions of X-chromosomes.

I have used[16] dispermic androgenesis to construct males doubly heterozygous for X linked lethals. These males, when crossed to females, gave a sex ratio of 98.6 males to 1.4 females.

A more efficient method of producing males heterozygous for two different lethals on their X chromosomes has been developed using a translocation of the left end of the X chromosome on the Y chromosome. The translocated portion of the X carries the wild type alleles of both lethals and translocation bearing females are fertile despite the sex chromosome aneuploidy. The genetic programme for making the balanced lethal stock is shown in Fig. 3. Females of the balanced stock all carry the X:Y translocation and a normal X chromosome marked with either lethal 1 or lethal 2. The males are all heterozygous for both lethal 1 and lethal 2. This stock breeds true but when the males are outcrossed to wild type females nearly all female zygotes die as a result of the expression of either one of the lethals. The 0.1% or so females that survive do so as a consequence of recombination between the lethal loci.

The use, for silk production, of hybrid strains which produce entirely males will greatly benefit silk yield. Both the Y:10 and X:Y translocations described have been introduced into commercial breeds of the silkworm and are being used in commercial breeding in the Soviet Union.

Interaction between the daily heat balance and the tidal cycle

H. F. Vugts

Department of Meteorology, Institute of Earth Sciences, Free University, PO Box 7161, Amsterdam-11, The Netherlands

J. T. F. Zimmerman

Netherlands Institute for Sea Research, PO Box 59, Texel, The Netherlands

In a sea area consisting partly of periodically drying tidal flats, the semidiurnal lunar tide, interacting with the daily variation of solar radiation, gives rise to both a beat in the amplitude of the daily water temperature cycle with a period of 14.76 d, and a variation of the daily mean temperature, with the same period. This is shown theoretically and by observation.

IN general, the frequency spectrum of temperature fluctuations at the Earth's surface is dominated by annual and daily frequencies and their higher harmonics. These peak frequencies of the spectrum originate from, and can be computed from, the variation of solar radiation at a given latitude[1]. The rest of the spectrum can be attributed to 'atmospheric noise' (such as varying cloudiness and advection of different air masses, for instance by depressions, interchanging heat with the Earth's surface).

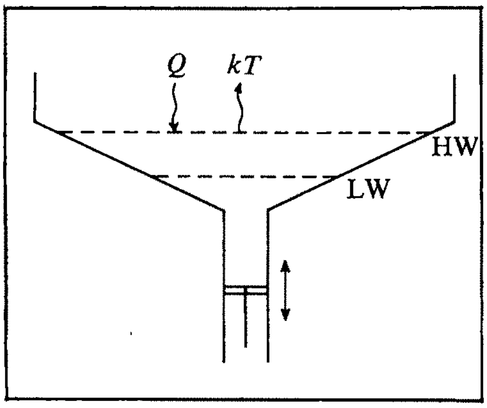

Fig. 1 Sketch of the model experiment described. HW, high water; LW, low water.

With respect to the sea surface the advection by periodic currents, such as those produced by the tides, may, in a non-homogeneous temperature field, also produce a peak in the frequency spectrum; the frequency being the same as that of the current involved if the temperature is measured in a frame of reference fixed to the sea floor. The latter fluctuations, however, disappear if the temperature is integrated over an area large as compared with the scale of the periodical currents.

This shows that the latter fluctuations arise from an internal redistribution of waterparcels but not from an external forcing agent such as the absorption of solar radiation and heat exchange with the atmosphere. It is, however, possible that in certain areas periodic (tidal) currents produce externally forced temperature fluctuations with frequencies that are sums or differences of the tidal and daily frequencies and their higher harmonics. This will be the case in those areas along the coast, where the effect of the tide is to produce a periodic flooding of tidal flats. This causes a periodical change in the surface area through which solar radiation penetrates and heat is exchanged with the atmosphere.

Knowledge of the heat balance and temperature cycle of such a tidal-flat sea is relevant to the biology of these areas; temperature is one of the most important physical factors in its ecosystem. Moreover, in planning power stations which will discharge heated effluents in areas of tidal flats, the special character of the heat balance should be taken into account.

Theoretical considerations

In a sea which covers tidal flats the tidal currents cause both a periodical translation of water masses and a periodical flooding of the tidal flats. In consequence, the area of interface between the sea water and the atmosphere will differ during different phases of the tide. At low tide a given volume of water will collect in deeper tidal channels and will thus have a smaller surface area than at high tide when part of the same volume will be spread out over the tidal flats.

To study the influence of such a periodically varying surface area on the heat balance of the water volume, we have devised a simplified model experiment which is assumed to represent the real situation in a tidal-flat sea.

The floor of a reservoir containing a volume V, of water of density ρ and specific heat c, slopes gently from the sides towards a hole in the middle (Fig. 1). The surface area of this volume of water can be varied by working a piston contained in a tube under the hole, up and down with a frequency, ω_2. The amplitude of the piston displacement is such that the water surface never reaches the sides of the reservoir and never becomes as small as the cross section of the hole. It is supposed that there is a varying absorption of (solar) radiation and a varying heat exchange between the water volume and the overlying air. Furthermore, it is assumed that the volume is well mixed in all directions so that it has at any moment a uniform temperature, T. The heat flux density, Q, through the water surface is then approximately given[2] by:

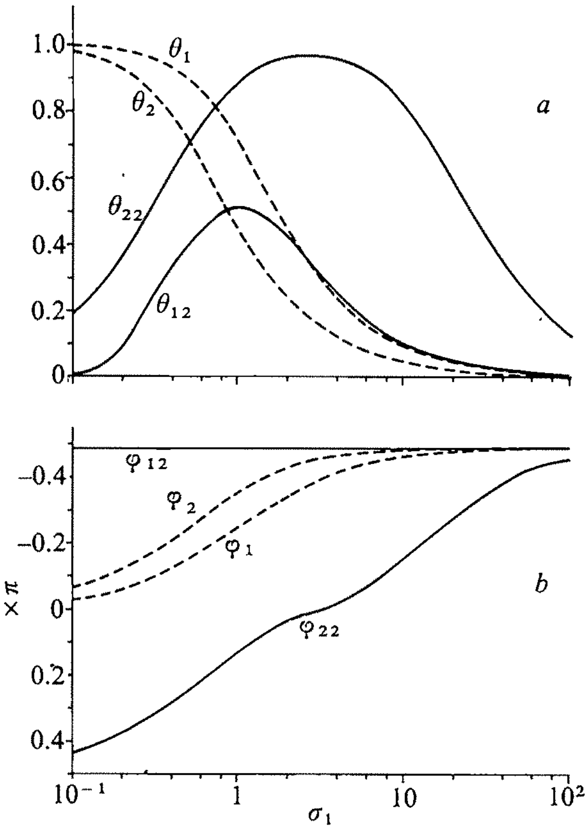
$$Q(t) = \sum_{n=-\infty}^{n=\infty} q_n \exp(in\omega_1 t) - kT(t), \quad q_n = q^*_{-n} \qquad (1)$$

where q_n is a (complex) amplitude of the Fourier series in $\omega_1 t$ (ω_1 is the daily frequency). The factor k is a bulk parameter[2,3] representing all the processes by which heat is exchanged with the atmosphere, such as long wave radiation, (turbulent) conduction, and evaporation. In general, k will be time dependent, but here it is assumed to be a constant. For $n \neq 0$ q_n contains both the daily variations in solar radiation and the effects of daily fluctuations in air temperature, humidity and wind velocity. We will, however, assume that these latter effects are of minor importance so that $q_n (n \neq 0)$ is only determined by the daily variation in solar radiation. Then, for a cloudless sky, q_n can be obtained easily for a given latitude and time[1]. For $t = 0$ at midnight, all q_n are real whereas for odd absolute values of n greater than 1 they are zero. For $n = 0$, q_0 represents the constant part of the heat income. It is, however, only approximately a constant because it varies during the course of the year and, on a smaller time scale, because of varying atmospheric conditions. It follows from equation (1) that the equilibrium daily mean temperature of the water mass is given by q_0/k (refs 2 and 3). We will assume that T represents the deviation of the water temperature from this equilibrium value.

Now, the rate of change in temperature of a volume, V, is given by:

$$\frac{dT}{dt} = \frac{Q(t).S(t)}{V\rho c} \qquad (2)$$

Fig. 2 *a*, Real, dimensionless temperature amplitudes; *b*, phase angles.



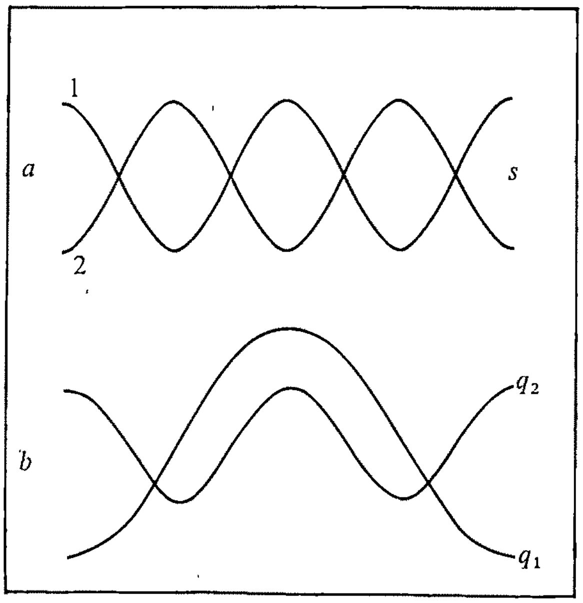


Fig. 3 *a*, Variation of surface area, *s*, during a day for two days separated by a time interval of seven days; *b*, variation during the day of the first and second harmonic constituents of solar radiation, q_1 and q_2.

Let $S(t)$ be given by:

$$S(t) = S_0[1+s_1 \exp(i\omega_2 t)+s_{-1}\exp(-i\omega_2 t] \qquad (3)$$

where $s_1 = s^*_{-1}$, and $2|s_1| < 1$

Without loss of generality $s_{1,-1}$ can be assumed to be real as long as $\omega_2 \neq n\omega_1$. We suppose ω_2 to represent the frequency of the semidiurnal lunar (M_2) tide.
Equations (1) – (3) give:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \left[\sum_{n=-\infty}^{n=\infty} q_n \exp(in\omega_1 t) - kT\right] \times$$

$$\times \left[1 + s_1 \exp(i\omega_2 t) + s_{-1} \exp(-i\omega_2 t)\right] / h\rho c \qquad (4)$$

where $h = V/S_0$ denotes the effective mean depth of volume V. Equation (4) is a first order non-homogeneous differential equation for T with a periodic coefficient of T and a driving term containing the frequencies $n\omega_1$ as well as their sums and differences with ω_2. We shall focus attention on the first and second harmonics of the daily frequency and their interaction with the tidal frequency, ω_2, as far as these interactions have frequencies smaller than ω_2. Thus, only the frequencies ω_1, $2\omega_1$, $\omega_2-\omega_1$, $2\omega_1-\omega_2$ are considered here, to which respectively the complex amplitudes T_1, T_2, T_{12} and T_{22} are ascribed. The latter can be obtained by inserting in equation (4):

$$T = T_1 \exp(i\omega_1 t) + T_2 \exp(2i\omega_1 t) + T_{12} \exp(i(\omega_2-\omega_1)t) + T_{22} \exp(i(2\omega_1-\omega_2)t) + \text{complex conjugates} \qquad (5)$$

and collecting terms with the same frequency. It is necessary to introduce several other quantities.

- $\tau = h\rho c/k$, a relaxation time[2,3] representing the thermal inertia of a water mass.
- Dimensionless frequencies $\sigma_1 = \omega_1\tau$ and $\sigma_2 = \omega_2\tau$.
- The frequency ratio $r = \omega_2/\omega_1$ $(1 < r < 2)$.
- Dimensionless real temperature amplitudes

$$\theta_1 = k|T_1/q_1|,\ \theta_2 = k|T_2/q_2|,\ \theta_{12} = k|T_{12}/s_1 q_1|,\ \theta_{22} = k|T_{22}/s_1 q_2|.$$

- Phase angles: $\varphi_1 = \arctan\,(Im[T_1]/Re[T_1])$ and φ_2, φ_{12} and φ_{22}. The solution for the θs and φs can be expressed in σ_1 and r and read, in first approximation:

$$\theta_1 = (1+\sigma_1^2)^{-\frac{1}{2}},\quad \varphi_1 = -\arctan\sigma_1$$

$$\theta_2 = (1+4\sigma_1^2)^{-\frac{1}{2}},\quad \varphi_2 = -\arctan 2\sigma_1$$

$$\theta_{12} = \sigma_1\,[\{1+\sigma_1^2\}\,\{1+\sigma_1^2\,(1-r)^2\}]^{-\frac{1}{2}}$$

$$\varphi_{12} = -\arctan\frac{1-\sigma_1^2\,(1-r)}{\sigma_1\,(2-r)}$$

$$\theta_{22} = 2\sigma_1\,[\{1+4_1^2\}\,\{1+\sigma_1^2\,(2-\mathrm{r})^2\}]^{-\frac{1}{2}}$$

$$\varphi_{22} = -\arctan\frac{1-2\,\sigma_1^2\,(2-r)}{\sigma_1\,(4-r)}$$

These functions are shown in Fig. 2*a* and *b* for $r = 1.932$, corresponding to the ratio of the tidal (M_2) frequency and the daily frequency. As k may vary[3] between 10 and 60 W m^{-2} K^{-1} and, for a tidal-flat sea, $0.1 < h < 10$ m is a representative interval, the range of interest for σ_1 will be $10^{-1} - 10^2$.

The components with the daily frequency and its second harmonic (θ_1, φ_1 and θ_2, φ_2) are the same as in the case of a water mass with a stationary surface area[2,3]. For $\sigma_1 \rightarrow 0$, $\theta_1 \rightarrow 1$ and $\theta_2 \rightarrow 1$, whereas $\varphi_1 \rightarrow 0$ and $\varphi_2 \rightarrow 0$, indicating that for increasing exchange factor k or decreasing depth or frequency the instantaneous water temperature approaches its instantaneous equilibrium temperature, defined by $Q(t)/k$, as it ought to be for a water mass with a very small thermal inertia.

The temperature fluctuations caused by the interaction of the daily heat balance and the tidal cycle have a maximum, however, if $\sigma_1 = 1.0$ and $\sigma_1 = 2.5$. In other words, if the relaxation time, τ, is of the same order of magnitude as the daily period. In contrast to the amplitudes for the daily frequency and its higher harmonics, the interaction amplitudes tend to zero for $\sigma_1 \rightarrow 0$. This should be so, as for a water mass which approaches at any moment its equilibrium temperature the variation of its surface area does not matter.

If ω_2 represents the M_2 tidal frequency, frequencies $\omega_2-\omega_1$ and $2\omega_1-\omega_2$ are, respectively, 6.780×10^{-6} and 4.925×10^{-6} rad s^{-1}. Therefore, one of the consequences of the interaction will be a long-period temperature variation with a frequency of $2\omega_1-\omega_2$ or a period of about 14.76 d. This will be observed as a variation of the daily mean water temperature.

The other interaction frequency $(\omega_2-\omega_1)$ corresponds to a period of about 25 h 42 min, somewhat larger than the daily period. As a consequence of the summation of trigonometric functions with slightly different periods, the sum of the temperature fluctuations with daily frequency and interaction frequency $(\omega_2-\omega_1)$ will be observed as a beat in the amplitude of the daily temperature cycle with a period of about 14.76 d. This can be seen as follows. If for $\exp(i(\omega_2-\omega_1)t)$ is written $\exp(-i(2\omega_1-\omega_2-\omega_1)t)$ we get for the daily temperature cycle:

$$\{T_1+T_{12}\exp[-i\,(2\omega_1-\omega_2)t]\}\exp(i\,\omega_1 t) + \text{complex conjugate}$$

Thus, the amplitude of the daily cycle reads:

$$2|T'_1| = 2\{T_1T^*_1+T_{12}T^*_{12}+T_1T^*_{12}\exp[i(2\omega_1-\omega_2)t] + T^*_1T^*_{12}\exp[-i\,(2\omega_1-\omega_2)\,t]\}^{\frac{1}{2}}$$

which is simply an amplitude varying with frequenc $2\omega_1-\omega_2$ or with a period of about 14.76 d.

The phenomenon of the interaction of the daily heat balance and the tidal cycle can be understood from Fig. 3. Here, for two days separated by a time interval of seven days, the variation of surface area (s) because of the M_2 tide is shown together with the first and second harmonic constituents of the solar radiation (q_1 and q_2). In case 1 the maximum and minimum of

Table 1 Real temperature amplitudes (°C)

h (cm)	$2\lvert T'_1\rvert$		$2\lvert T_2\rvert$	$2\lvert T_{22}\rvert$
	max	min		
10	3.62	3.15	1.06	0.33
50	1.39	1.13	0.25	0.40
100	0.73	0.56	0.13	0 39
250	0.37	0.24	0.08	0.29
500	0.18	0.14	0.03	0.19
1,000	0.09	0.07	0.02	0.10

q_1 coincide approximately with the maxima of the water surface, whereas in case 2 they occur at its minima. The consequence is a variation in the amplitude of the daily temperature cycle with a period of 14.76 d. As for the second harmonic, q_2, the maxima coincide with the maxima of s in case 1 and with the minima of s in case 2. Thus, in the first case there is a daily mean input of energy from this harmonic constituent whereas in the second case there is a daily mean output of energy. This causes a fluctuation of the daily mean temperature with a period of 14.76 d too.

In order to illustrate the theory we give a numerical example (Table 1) showing the values of the different real amplitudes for different depths of a tidal-flat sea. The values chosen for the parameters are: $k = 50 \text{ W m}^{-2} \text{ K}^{-1}$, $2|q_1| = 3\pi\ |q_2|/2 = 200 \text{ W m}^{-2}$, $2|s_1| = \frac{1}{2}$.

The interaction effects have a magnitude (Table 1) which is certainly sufficient to be detected with relatively simple techniques of measurement and which are, possibly, not without interest for ecological problems.

Of course, the interaction of the M_2 tide with the semidiurnal solar tide (S_2) does give rise to a spring–neap tidal cycle in the tidal range, which has the same period as the variation of the daily mean temperature and of the daily amplitude, explained here by the interaction of M_2 tide and solar radiation. Our explanation remains valid if an S_2 tide is present in the variation of surface area. In that case, the S_2 tide produces an apparent change in amplitude and phase of the temperature variations with daily frequency and higher harmonics. The existence of an M_2 tide interacting with solar radiation remains necessary, however, to explain the appearance of the 'new' frequencies $\omega_2-\omega_1$ and $2\omega_1-\omega_2$, and, consequently of the varying daily mean temperature and amplitude.

Real situation

Until now, there have been no systematic surveys of temperature fluctuations in tidal-flat seas. We have made extensive measurements in the Dutch Wadden Sea, which is part of an estuarine inshore area along the Dutch, German and Danish coasts, separated from the North Sea by a chain of islands. An important part of the area called 'Wadden', emerges at low tide as muddy sand flats. A typical part of this tidal-flat sea is the Mok bay, situated at the southern tip of Texel Island (Fig. 4). A tidal channel connects the bay with the western part of the Wadden Sea. Through this channel water which covers the tidal flats flows in and out with the tide. The mean volume of the bay is about 10^6 m^3; the area of the tidal flats, including the tidal channel, amounts to 8×10^5 m^2. The tide in this area is dominated by the M_2 tidal cycle. There is also an obvious spring–neap tidal cycle. The latter, however, has only a minor effect on the fluctuation of the surface area as, because of the geometry of the bay, high tide surface area and low tide surface area are approximately the same at spring tide and at neap tide.

In the tidal channel (Fig. 4b) the temperature was recorded at three different depths, at intervals of 5 min. For the purpose of this study, records taken at intervals of 15 min were sufficient. On that basis, the daily mean temperature was calculated. At one of the tidal flats all of the relevant meteorological parameters were recorded; these included net radiation, air temperature, humidity and wind velocity. The accuracy of water temperature measurements was checked with reversing thermometers, and seemed to be 0.1 °C. Measurements were carried out over three periods: April 21–May 5, 1972; August 22–September 21, 1973 and June 21–August 29, 1974. Thus, about 110 days of records were available for analysis As is to be expected in this area, daily mean values and daily amplitudes of water temperature varied greatly. To demonstrate that the records contain periodicities induced by the tide, as predicted by theory, 6 periods, each covering 15 d, were considered.

To separate short-term variations of the daily mean water temperature, including tidal effects, from background, long term fluctuations, such as increases or decreases of water temperature caused by seasonal heating or cooling, the daily mean difference between the temperature of the channel and that of the adjacent North Sea was calculated. For the latter, water temperature measurements taken from the lightship Texel (Fig. 4), positioned about 20 miles from Mok Bay, were used. These are thought to be influenced by long term meteorological processes, but not by the effects of the tidal flats.

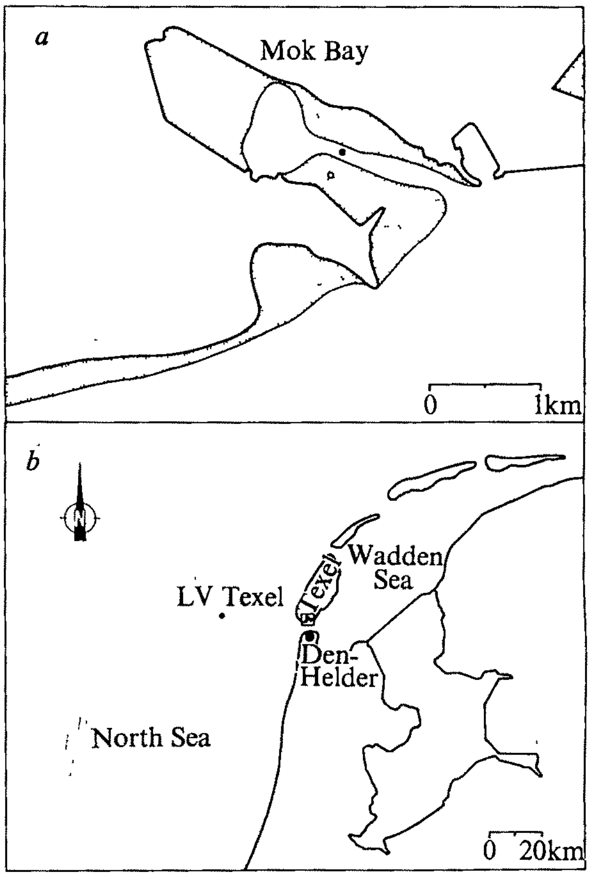
Next, for each of the six periods, a smoothed curve of the temperature differences was obtained using the formula: $\bar{X}_i = \frac{1}{4}(X_{i-1}+2X_i+X_{i+1})$, where $\bar{X}_i$ is the smoothed value for the ith day and X_{i-1}, X_i, X_{i+1} are daily mean values.

Then, for each of the six periods a straight line was drawn through the smoothed values by least-squares fit, to account for any trend during the period of 15 d. For each day in a particular period the deviation from this line was taken.

Finally, the last values were normalised for each period by dividing through the mean of the absolute values of the positive and negative extreme deviation from the least-squares-fit line.

After normalising the six periods, an average curve for each 15-d period was constructed in such a way that days having high tides at approximately the same time as one another occupied the same place in the sequence. The resulting curve, dimensionless by normalising, was transformed back to daily deviations in °C, from the period mean.

Fig. 4 Situation of the Mok Bay on large (a) and small (b) scale. The former shows the points of registration of meteorological parameters (○) and water temperature (●).



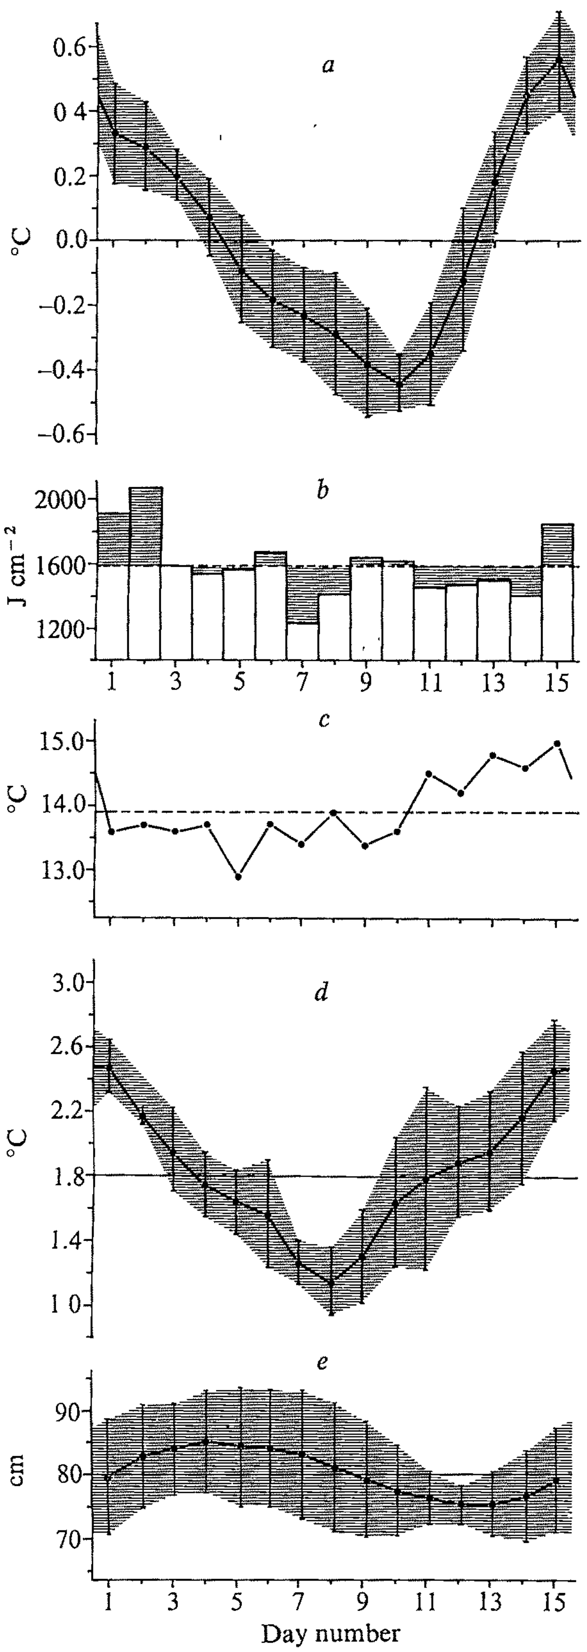


Fig. 5 *a*, Average curve of the deviation of daily mean water temperature of Mok Bay from its mean value over a 15-d period, showing also standard-deviation bars; *b*, average variation of global radiation over a sequence of 15 days; *c*, average curve of the daily mean air temperature; *d*, average curve of the difference between daily maximum and minimum water temperatures of the Mok Bay, showing also standard-deviation bars; *e*, average curve of high tide level in the Mok Bay over a sequence of 15 days; bars denoting the standard deviations.

The result is shown in Fig. 5*a*. There is a significant difference between the temperature deviation curve and any straight line and the curve agrees well with the predicted periodicity of the daily mean water temperature in a tidal-flat area.

To show that this result is not caused by an accidental variation of the energy input (q_o), having the same period, average values of global radiation, which constitutes the most important part of q_o, were calculated. For this we have taken values measured at Den Helder (Fig. 4*a*) by the Royal Netherlands Meteorological Institute. The mean global radiation for the 90 d used in the analysis is 1,585 J cm^{-2} d^{-1}. The average deviation for each day of the 15-d periods is shown in Fig. 5*b*. It is clear that there is no correlation between the variations in global radiation and the curve of Fig. 5*a*. For the same purpose this procedure was carried out for the air temperature. The mean air temperature for the 90 d, observed at land station Den Helder, supposed not to be influenced by any tidal effect, was 13.9 °C. The air temperature curve averaged over six periods is drawn in Fig. 5*c*. As for the global radiation, there is no apparent correlation between the average daily air temperatures and the curve of Fig. 5*a*.

The asymmetrical behaviour of the curve of Fig. 5*a* could be explained by the fact that, in this area, the moment of high tide itself shifts in an asymmetrical way during a 15-d period. Of course, part of the asymmetry may be caused by a variation in the atmospheric background, which has not been removed by averaging over only six periods.

As predicted theoretically, the daily amplitude varies with a period of about 15 d as well. As the maximum and minimum water temperatures are strongly dependent on weather conditions, the procedure used here to calculate the daily mean water temperature was used, without the first step and with a more extensive smoothing formula[4]:

$$\bar{X}_t = \tfrac{1}{35}[17X_t + 12(X_{t+1} + X_{t-1}) - 3(X_{t+2} + X_{t-2})]$$

To obtain the daily maximum and minimum water temperatures the mean values of the 5 highest and of the 5 lowest values of the daily records were taken (Fig. 5*d*). From this figure it may be concluded that the daily amplitude shows a periodic behaviour in agreement with theoretical prediction.

There is no need to regard the spring–neap tidal cycle as responsible for the results presented here, rather than the interaction of the M_2 tide and solar radiation. To illustrate this, we have shown (Fig. 5*e*) the average curve of the high tide level in the Mok Bay during a 15-d sequence. There is indeed a slight spring neap tidal cycle visible. Note, however, the large standard deviations which are caused partly by influences on water level other than those of the astronomical tides. The figure demonstrates, at least, that the maximum of the daily amplitude does not occur at spring tide and that the minimum does not coincide with neap tide. The same applies to the comparison of Fig. 5*a* with Fig. 5*e*.

The variation of the daily mean water temperature is about 0.9 °C, whereas the daily amplitude varies from 0.6 to 1.2 °C. These values are not in agreement with Table 1 if the mean depth is assumed to be about 100 cm. The numerical disagreement is probably caused by the great difference in geometry between the idealised theoretical model and the complicated tidal-flat area of the Mok Bay. Moreover, in theory a well mixed basin was assumed, whereas in reality temperature distribution in the Mok Bay is not uniform. Consequently, advection by tidal currents will affect the temperature variation, influencing especially the daily amplitude. None the less, it may be stated that a qualitative agreement exists between theory and experiment.

Long-range transport of photochemical ozone in north-western Europe

Measurements of the concentrations of ozone and trichlorofluoromethane in the atmosphere over various parts of the southern British Isles provides evidence to suggest that photochemical ozone and the pollutants from which it is formed may be transported into the region from their origins in continental Europe. It seems likely, therefore, that even isolated areas, away from centres of industrialisation, may suffer the effects of this pollution.

THE concentration of ozone in air at ground level increases during sunny, anticyclonic weather[1-3]. The maximum hourly concentrations of 0.11–0.12 p.p.m. are 2–3 times as high as expected in unpolluted air near to the ground. This suggests that photochemical ozone is widespread and is not confined to localities in which pollutants such as oxides of nitrogen and hydrocarbons are emitted.

In 1973 the ozone concentration was measured at three widely spaced locations on an E–W line across southern England and Ireland. The sites (Table 1) were in rural areas away from large, local sources of pollution and also away from forested areas and other sources of natural hydrocarbons. The most remote site, at Adrigole, was chosen in the expectation that it would provide a measure of the 'background' level of ozone concentration for the maritime regions of north-western Europe. Meteorological data were obtained from nearby meteorological stations (Table 1). In addition, local meteorological conditions at Harwell were recorded on an automatic weather station at the sampling site.

The ozone concentration was measured continuously using ethylene-chemiluminescence monitors. Ambient air was sampled at a height of 2 m above ground through polytetrafluorethylene tubing. A filter was used to prevent the entry of particulate matter into the detector and flow-control systems. The detectors were calibrated using a constant ozone source standardised with neutral-buffered, potassium iodide solution[4]. Regular checks on the calibration of the instruments at Harwell and Sibton revealed no significant drift in the zero or full-scale settings over the period of measurement. Routine calibration checks on the Adrigole instrument could not be made. The net change in sensitivity was, however, less than 10% over 5 months. Any zero drift was corrected by automatically recording the photo-multiplier dark current once every hour.

The concentrations of halogenated hydrocarbons as well as of ozone were measured at Adrigole. Air samples were taken twice daily, at 0500 and 1400, on an automatic gas chromatograph equipped with an electron capture detector operating in the coulometric mode[5]. The chromatograms were recorded on a strip chart from which absolute concentrations of CCl_3F and CCl_4 were determined at a later date. Similar measurements were made at Bowerchalke, Wiltshire (90 km south-west of Harwell) and using those results in conjunction with the Adrigole measurements we obtained information on the history of air masses over the southern British Isles at any given time. The trajectories of air masses were computed backwards in time for Adrigole and Sibton. These air trajectories were based on mean winds, computed for the layer 300–2,000 m above the average terrain using a Northern Hemisphere radio sonde observation data set. Each wind vector in the area around the point of interest was weighted by $1/R^2$ where R is the distance between the observing station and the point of interest. A 'central tendency' extrapolation scheme was used to trace the 'air' back in time.

Table 1 Latitudes and longitudes of sampling locations

Sampling location	Position	Meteorological stations
Adrigole, County Cork, Ireland	51°40′N 9°45′W	Valencia
Harwell, Oxfordshire, England	51°35′N 1°19′W	Heathrow
Sibton, Suffolk, England	52°03′N 1°05′E	Gorleston

Trajectories for all four synoptic times (0000, 0600, 1200, and 1800 GMT) were constructed, but only those for midday (1200 GMT) are considered here. The trajectories for Adrigole were carried backwards in time for a maximum of 5 d (120 h) which usually complied with the prescribed space limitations for wind vector interpolation.

At Sibton, it was possible to estimate the trajectories up to a maximum of 10 d (240 h) before the arrival of the 'air'.

Results and discussion of daily measurements

The maximum hourly mean ozone concentrations at th observation stations during each day are shown in Fig. 1. Th concentrations of CCl_3F at Adrigole and Bowerchalke are als shown. CCl_3F is an inert anthropogenic gas, and its concentra tion gives an index of pollutants in an air mass.

Ozone. Table 2 gives the frequency distribution of maximun hourly mean concentration of ozone. The range (0.03–0.1 p.p.m.) was similar at all three sites and, surprisingly, th number of days on which the US standard[3] of 0.08 p.p.m. w exceeded at Adrigole (17 days) was similar to that at Harwe

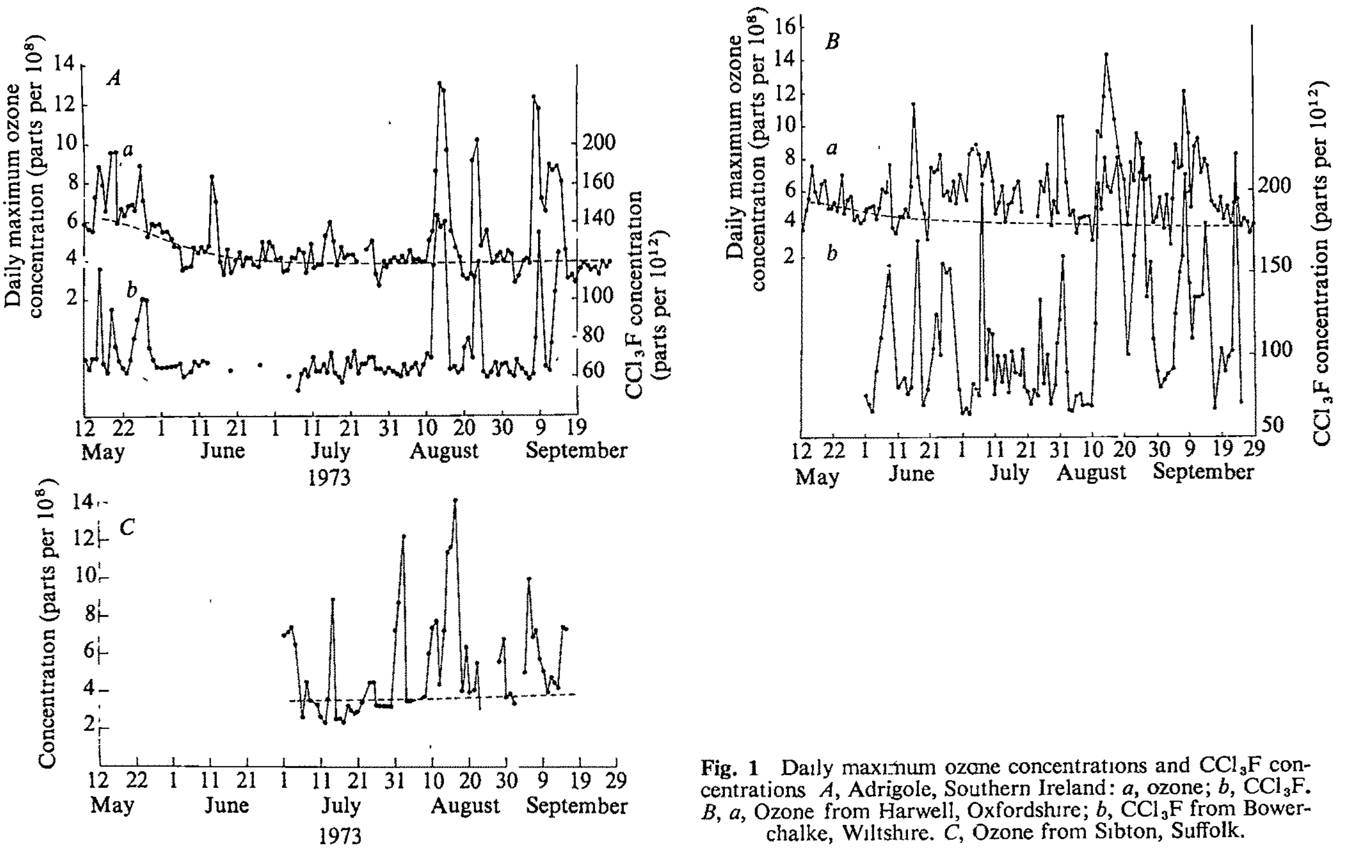

Fig. 1 Daily maximum ozone concentrations and CCl_3F concentrations *A*, Adrigole, Southern Ireland: *a*, ozone; *b*, CCl_3F. *B*, *a*, Ozone from Harwell, Oxfordshire; *b*, CCl_3F from Bowerchalke, Wiltshire. *C*, Ozone from Sibton, Suffolk.

(23 days) although Adrigole is much further from sources of the precursor pollutants than Harwell.

Incidents of elevated ozone concentration superimposed on a 'background' level (Fig. 1) are clearly indicated at each site. We believe this 'background' level represents the natural ozone content of the lower troposphere over north-western Europe.

The mean background concentration at Adrigole was about 0.04 p.p.m. compared with 0.03 p.p.m. at Mauna Loa and 0.02 p.p.m. at Point Barrow, Alaska (both in September, 1973).

The pattern of the incidents, particularly during August and September was similar at each of the three sites.

Fluorocarbons. The general pattern of the fluorocarbon concentrations was very similar to the maximum hourly mean ozone concentration data — values varied in southern England but stayed near background level for longer periods at Adrigole. The background concentration of CCl_3F at Adrigole was 68 parts per 10^{12} by volume (calculations were based on concentrations observed when the air masses were coming from the Atlantic). In polluted air, concentrations of up to 370 parts per 10^{12} by volume were observed. Figure 1 shows clearly that ozone and CCl_3F were advected in polluted air over south-western Ireland. Comparisons of ozone concentrations at Harwell with CCl_3F concentrations at Bowerchalke shows the same thing.

The correlation coefficient between CCl_3F and O_3 at Adrigole was 0.74, based on measurements taken at 1400 GMT May–September, 1973. The higher values ($CCl_3F > 100$ parts per 10^{12} by volume; $O_3 > 0.1$ p.p.m.) were deleted and the correlation recomputed, resulting in a reduced correlation coefficient of 0.49.

We conclude that a significant portion of the ground-level ozone in southern England during the summer is anthropogenic in origin and that in suitable meteorological conditions ozone and/or its precursors can be transported over distances of the order of 100–1,000 km, to give appreciable levels of pollution in locations far from the source.

Diurnal variation in ozone concentration

Figure 2 shows the diurnal variation of ozone at all three sites during August 11–18, 1973. Figure 3 shows the frequency distributions of the daily maxima as a function of time of day over the whole period of measurements at Harwell and Adrigole. At Harwell and also at Sibton, there were consistent daytime maxima and nocturnal minima. There was no marked diurnal variation at Adrigole. On several occasions maxima occurred during the night.

At inland stations shallow nocturnal inversions are common, particularly during anticyclonic weather in summer. Ozone is destroyed at the Earth's surface, and may also be removed by gas-phase reactions with other pollutants. Below an inversion, the downwards diffusion of ozone from above is inhibited, and thus the concentration can be expected to fall. During the day, convection is strong, more ozone is brought down, and the concentration rises. Adrigole is on a peninsula and is only

400 m from the sea. At coastal locations, nocturnal inversions are less common. Moreover, ozone is destroyed more readily at land surfaces than at sea surfaces[6–8], thus, the difference in the patterns of diurnal variation between Adrigole and other sites can be explained. The diurnal pattern of photochemical ozone concentrations in urban areas has been attributed to the diurnal variation of insolation, with each day treated as an episode. Measurements at stations very near the coast may demonstrate the continuity of the photochemical process over several days.

Transport of ozone

During the period August 11–August 18, 1973 an anticyclone became established over the North Sea, replacing a south-westerly air flow from the Atlantic by a predominantly easterly flow of continental air over the southern British Isles. The stable weather, with nearly cloudless days was interrupted by the eastward passage of a weak cold front over the entire region during August 16 and 17, after which the air flow was predominantly westerly. The changes in air flow during the period are illustrated in the back-track air mass trajectories for Adrigole and Sibton (Fig. 4).

The ozone concentration data for August 11–18 (Fig. 2) show the presence of elevated ozone concentrations at all three sites by the time the arriving air masses had been in transit over the continent for at least 24 h. After the passage of the cold front and the advection of air directly from the Atlantic, the ozone concentrations declined again to near normal values.

It is clear that the elevated concentration of ozone observed during the episode at Sibton, situated 10 km from the Suffolk coast in sparsely populated country, must have had its origin in continental sources outside the UK. The trajectory and CCl_3F data also confirm that advection from the continent led to the high ozone concentration at Adrigole. Contribution from the UK was also negligible; the air mass trajectories, although less reliable than those at Sibton because of the paucity of observations nearby, back-track to the south-east, towards France. The sources of emissions giving rise to the high values at Harwell are less clear. The maximum levels observed at Harwell are, however, not significantly different from those at Sibton, Adrigole or even central London (0.136 p.p.m. on August 15, 1973) showing that by August 15 a sufficiently high concentration of pollutants had accumulated in air of continental origin to give similar elevated concentrations over much of southern Britain and Ireland, and probably over more extensive areas also. It is not possible, therefore, to distinguish the specific contribution to the total pollution of sources in the UK.

The data obtained at Adrigole show that elevated ozone concentration can be sustained in air masses several hundred kilometres from the sources of emissions, which in turn indicates a relatively long natural lifetime for ozone in the lower troposphere. The overnight persistence of the elevated ozone levels requires a lifetime of at least 10 h. Table 3 and Fig. 4 show that advection to Ireland required from 30–100 h.

Considering that the Adrigole values were approximately as high as those in England, this implies that the effective lifetime of ozone is of the order of 1–2 d. It is not possible from these limited data to disentangle the several factors controlling concentration (source strength, vertical dispersion, ultraviolet intensity, removal rates and so on). Table 3 shows, however, that the highest values at Adrigole on August 14, 1973 coincided

Table 3 Trajectory length (km) and transit time from European continent to Adrigole

Date	Time	O_3 (p.p.m.)	Length (km)	Time of transit (h)	Speed (km h^{-1})
13	1200	0.10	700	48	14.6
14	1200	0.12	700	33	21.2
15	1200	0.11	655	48	13.7
16	1200	0.05	1,310	96	13.7

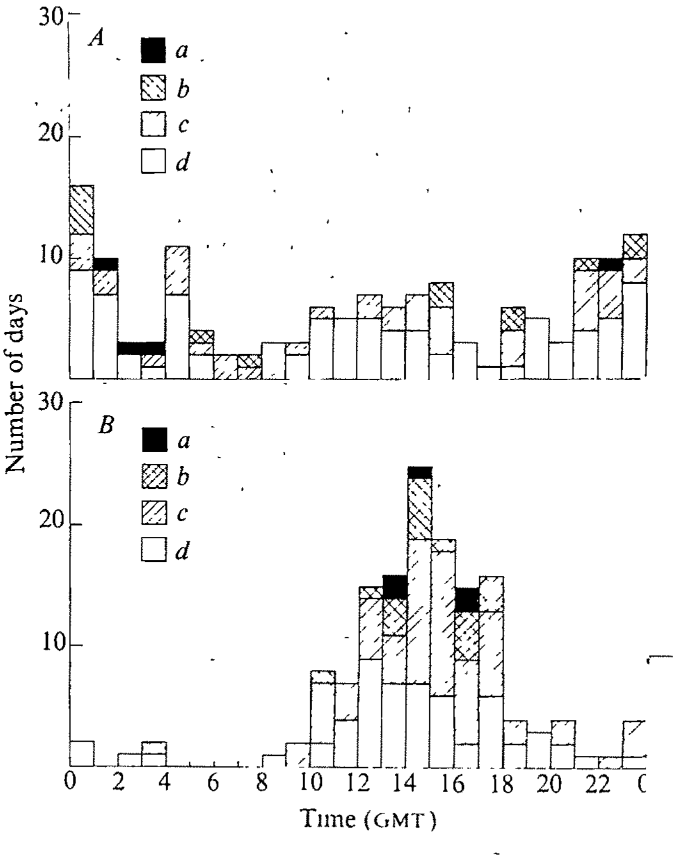

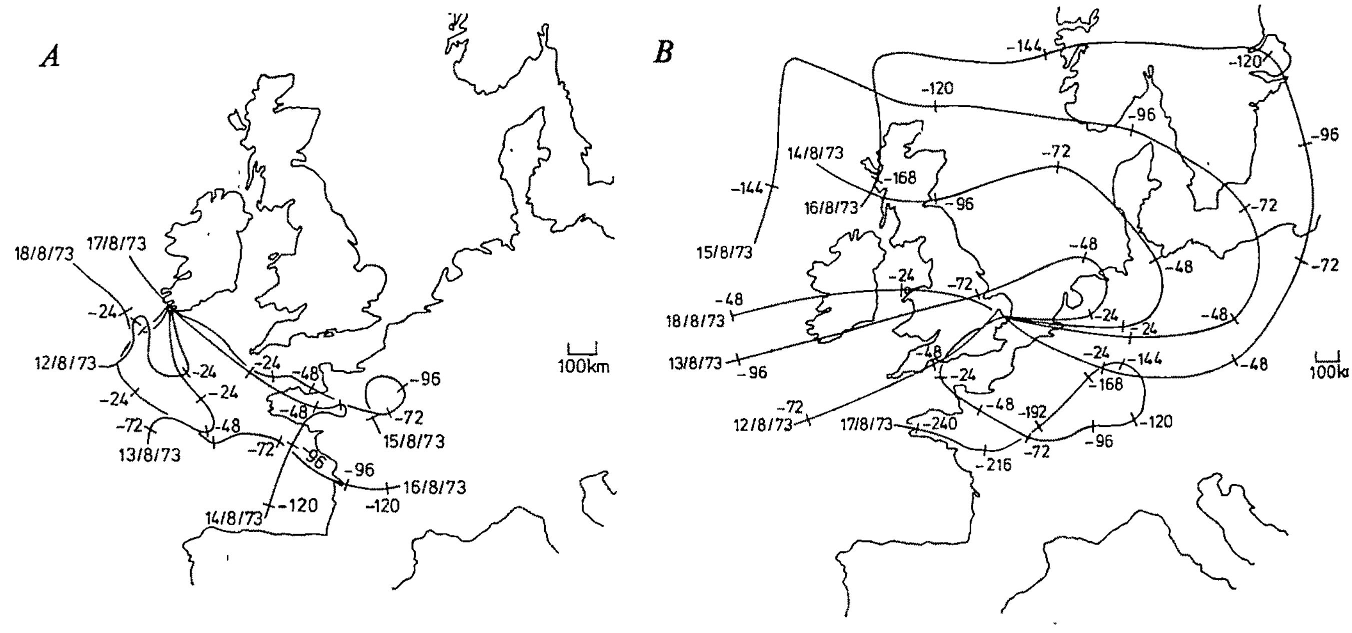

Fig. 4 Back-track air trajectories for 1200 GMT each day for Adrigole (*A*) and Sibton (*B*), together with position of air mass on preceding days.

with the shortest transit time over the sea; on August 16, however, the values, even before the frontal passage, had lowered by about 0.05 p.p.m. and were associated with trajectories and transit times twice those observed on August 14 and 15, 1973.

The alternative process of long range transport of pollutant precursors, with ozone formation occurring in response to local meteorology in each locality, is inconsistent with the high nocturnal ozone concentrations found at Adrigole. It would also require the formation of very similar ozone concentrations each day from what must be different precursor concentrations in Suffolk, central London, Oxfordshire and south-western Ireland.

We note, without comment on its relevance to the UK or Europe, that the US Air Quality Standard for photochemical oxidants was exceeded on a number of days during 1973 at all three sampling sites, including one situated in southern Ireland. We conclude that in suitable meteorological conditions measurable amounts of photochemical pollution of anthropogenic origin are transported over distances up to at least 1,000 km in north-western Europe and that on occasions continental emissions provide a major contribution to photochemical pollution in the UK. During such periods photochemical pollution is essentially a regional rather than local problem with uniformly elevated concentrations of photochemical ozone being observed simultaneously over different parts of the UK. It follows that, should controls on the emission of the pollutant precursors (hydrocarbons and nitrogen oxides) be considered necessary in order to reduce future levels of photochemical oxidants in the UK, then such controls are unlikely to be effective in the absence of similar controls elsewhere in Europe.

We are indebted to Mr Michael O'Sullivan and to the staff of Blyth Rural District Council, who maintained the monitoring equipment at Adrigole and Sibton, respectively. We thank the East Anglian Water Company for permission to use the Lodge Wood Water Tower, Sibton. Air mass trajectories were prepared by Mr J. Heffter of the Air Resources Laboratory. One of us (J. E. L.) thanks Shell Research Ltd. and the Manufacturing Chemists Association for financial support for part of this work. The ozone measurements at Sibton, Harwell and Adrigole were carried out as part of a programme of atmospheric pollution research sponsored by the UK Department of the Environment.

Construction of bacterial flagella

C. R. Calladine

Department of Engineering, University of Cambridge, Trumpington Street, Cambridge CB2 1PZ, UK

The flagella of Salmonella *can adopt a number of distinct helical forms. This article discusses the design of a subunit which packs to give a helical filament. Polymorphism is explained by small changes in the geometry of the subunit.*

BACTERIAL flagella are constructed from molecules of the protein flagellin by a process of self-assembly[1-6]. It is easy to see how a straight filament can be polymerised in this way, with the subunits arranged in a regular array in identical environments, as for example in tobacco mosaic virus[7]; but bacterial flagella in general have a helical shape, and it is hard to see how this can

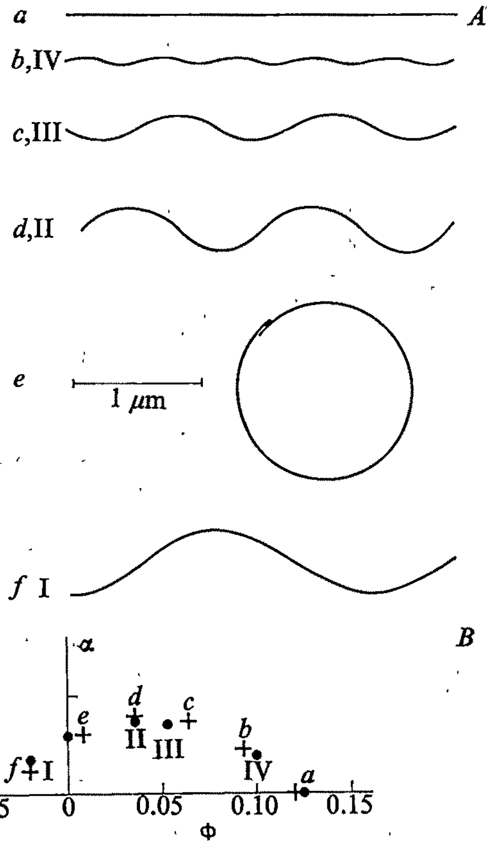

Fig. 1 *A*, Distinct helical forms made by copolymerisation of monomers *SJ 670* and *SJ814* (after Asakura[8,9]). Roman numerals are Asakura's identification, but lower case letters (*a–f*) are used for the corresponding theoretical classes proposed in this paper. Form *e* is circular, or closecoiled. Monomer *SJ670* can build *e* or *f*, and *c* and *d* if the *p*H is changed; and monomer *SJ814* can build *a* or *b*. Copolymerisation produces forms *b* ,*c* and *d*. The thickness of the filaments is roughly to scale. *B*, Curvature–twist plot for the six filaments shown in *A*. ●, Mean values from Asakura's[8,9] data (but twist of straight filament from O'Brien and Bennett[11]). +, Proposed model.

be achieved by bonding identical units to each other in a regular manner[3]. Furthermore, flagella of various strains of *Salmonella typhimurium* adopt, in different environments, a number of distinct polymorphic forms with different helical parameters[8,9].

I attempt to resolve this problem by designing a building block, within the framework of classical mechanics, which will assemble in quantity into a helical filament. This unit connects to six neighbours: four at an outer level, near the surface of the filament, and two at an inner level. When connected only by the outer contacts, the units can assemble into a family of distinct helical waveforms which correspond closely to those observed. The function of the inner connections between units is to select a particular member of the family. The model predicts a simple relationship between the total number of polymorphs and the number of longitudinal rows of subunits in the helical surface lattice.

Selected summary of present knowledge

The surface lattice of a bacterial flagellum is made up of a number of helical families, of which the most important are one-, five-, six- and eleven-start helices (Fig. 2*a*). This lattice is common to filaments from all strains so far investigated[10-12]. The main facts about the waveforms of the filaments have been reviewed by Asakura[8] and Asakura and Iino[9]. Figure 1*A* shows the distinct waveforms observed when flagella are constructed *in vitro* from monomer obtained from strains *SJ670* and *SJ814*, both separately and mixed[8,9].

From measurements on the waveform of a given filament it is possible to deduce, by simple geometry, the uniform twist and curvature which must be imported to the filament by the local building process. Here twist is described by the inclination φ (radians) of the longitudinal helices in the surface lattice to the local axis of the filament, and curvature α by the (percentage) difference in length between the longest and shortest of these longitudinal columns; I take the diameter of the filament, nominally, as 20 nm. It is useful to describe the results in the form of a plot of curvature against twist; Fig. 1*B* shows the data for the waveforms of Fig. 1*A*. The diagram incorporates recent observations[13] on the helical handedness of various waveforms. The circular filament has zero twist. In the case of a

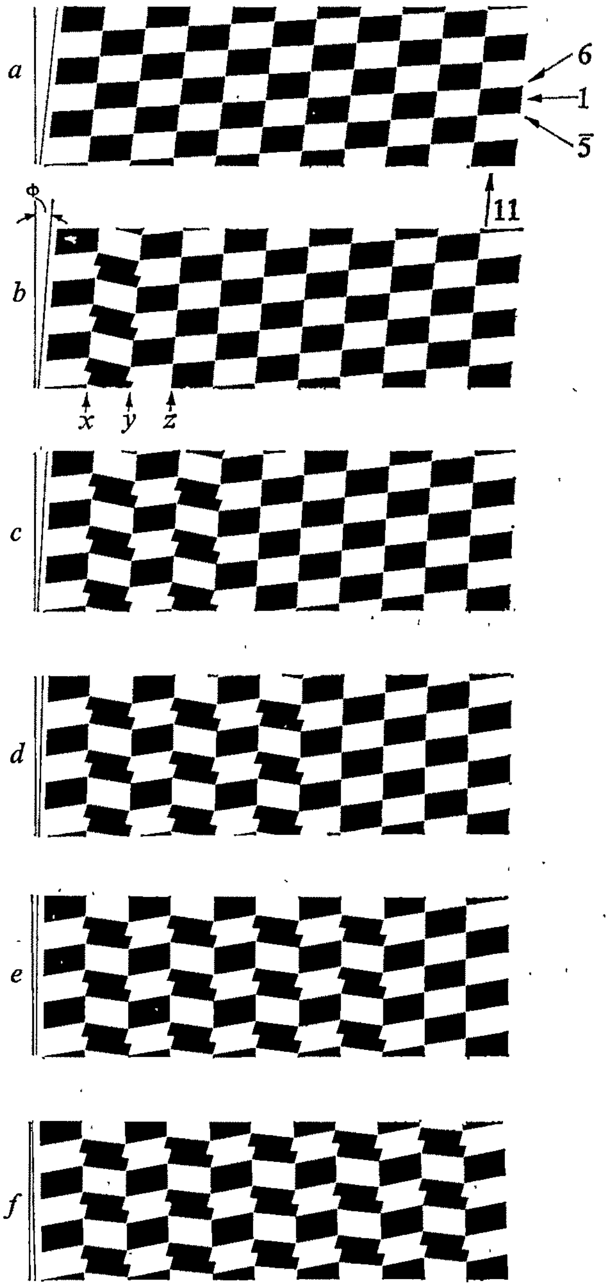

Fig. 2 Surface packings corresponding to the six ideal waveforms (*a–f*) viewed from the outside. The lower and upper edges of the patches each form a circle when the packings are wrapped into a cylindrical surface. A member of the one-, five-, six- and eleven-start helices in the surface lattice is picked out in *a*. Longitudinal (eleven-start) lattice lines make angle φ with the local axis; these two directions are shown at the left. Curvature is produced by small differences in axial length between 'strands', that is, lines of contacts, *x*, *y*, *z*, marked in *b*. Inner connections between units are not shown.

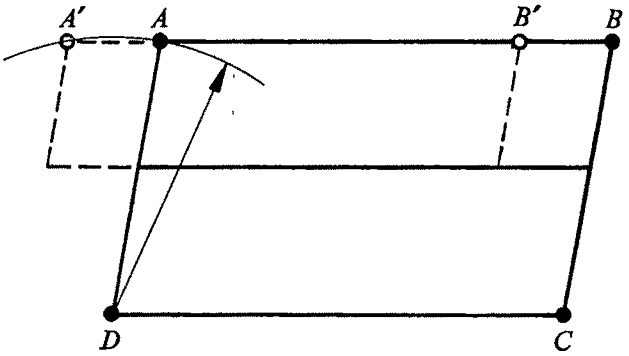

Fig. 3 Layout of connecting points on flat units in Fig. 4. ●, Normal connections; ○, alternative connections. The unit has two stable configurations involving relative motion of two parts of the unit, which are connected by interior bonds (not shown) having a bi-stable feature. The units fit exactly in the plane arrays of Fig. 2, but the design could easily be altered so that $A'D$ and $B'C$ are slightly less than AD and BC respectively.

straight filament the curvature is zero, and the twist can only be found from a knowledge of the surface lattice; O'Brien and Bennett[11] have found the twist of straight filaments of *SJ814* by high resolution electron microscopy using optical filtering techniques[14].

Surface packings and unit design

Consider the surface packings of identical flat units shown in Fig. 2. In *a* the interunit connections are at the corners of the quadrangular units, giving a uniform packing, but in *b–f* units in some columns have undergone a change in configuration which makes them rotate forwards. This change is here represented as a shear in the tetragonal disposition of the bonding sites (Fig. 3). The effect of rotation of units in a column is to shear the lattice along a nearly axial line of units, thereby altering the tilt of the columns with respect to the base-line, and thus changing the twist of the assembly. Each column so rotated gives an additive contribution to the twist of the assembly. A special feature is that rotated columns are clustered but are not adjacent to each other; I shall explain this later.

Now the two configurations of the unit shown in Fig. 3 are arranged so that the longitudinal dimensions are the same, that is, $A'D = AD$ and $B'C = BC$, and the units in the plane arrays of Fig. 2 fit exactly. It would be easy, however, to arrange for these dimensions to be slightly different, so that a longitudinal strand of connections such as x or y (Fig. 2*b*) is slightly shorter (say) than a strand z of regular bonding. If in addition the units are given a degree of longitudinal elasticity the units will assemble, in the round, to a curved filament. Indeed, with units having these features it is easy to show by the methods used for analysing thermal stress in elastic structures[15] (the difference in unstressed lengths of the strands being analogous to thermal expansion) that the curvature of filaments built according to the six patterns *a–f* is proportional to sin $2n\pi/11$, where n is the number of rotated columns, whereas the twist (relative to the twist for pattern *a*) is proportional to n. Hence a plot of curvature against twist gives a sinusoidal, discrete variation (Fig. 1*B*).

If we assign a reasonable degree of tolerance for the distortion of the filaments in the course of preparation for microscopy[8,9], we can see that the surface states *a–f* in Fig. 2 correspond closely to the waveforms observed by Asakura. This correspondence forms the basis of my proposed model.

Features of the surface packing

There are several crucial features of the packings shown in Fig. 2, without which the model would not work. First is the ability of the units to adopt two stable attitudes. The unit of Figs 2 and 3 has an internal movement controlled by a bi-stable 'switch' analogous to that already described[16] at the α–β interface in a haemoglobin molecule.

Second, each unit is connected to only four neighbours. A coordination number greater than this would inhibit the mechanism involved in changing between states in the surface arrays. This follows from the kinematics of interconnected rigid bodies: a full description will be given elsewhere.

Third, since the packings involve a chequerboard pattern, the longitudinal length of the assembly is determined by the strands of connections between adjacent columns of units (for example, x, y, z in Fig. 2*b*) rather than the individual columns themselves. This accounts (see next section) for some special features.

The notions that there are two inherently stable conformations of the subunit, and that different helical waveforms correspond to different numbers of longitudinal columns in the two states have been put forward by Asakura[8], and elaborated by Wakabayashi and Mitsu[17] who indeed did an elastic calculation on the curvature resulting from different numbers of columns in an alternative configuration. The absence of detailed consideration of interelement bonding from this analysis[17] (my crucial features two and three) however, prevented them from taking their model beyond a 'phenomenological' stage.

Why do 'rotated' columns cluster?

I have explained that the difference in the dimensions AD and BC between the two alternative configurations of the units gives a shortening of strands on one side of the filament and consequently a curvature. There is in fact a stringent geometrical requirement that the relative lengths of the strands of connections should vary sinusoidally around the circumference (Kirchoff's hypothesis[18]). Consequently each strand must be distorted a little from its natural long or short configuration to make it fit (except in case *a*). There will thus be an elastic strain energy of distortion[15] associated with any given packing, and it is easy to show quantitatively that, for a given number of columns in the alternative configuration, the strain energy is least when they are clustered precisely as shown in Fig. 2*b–f*. Figure 4 shows an example of this. The minimum is deep, and it is reasonable to suppose that this is why other packings are excluded.

Inner connections between the units

The outer connections described so far enable the units to assemble in regular packings like those of Fig. 2*a* but having an

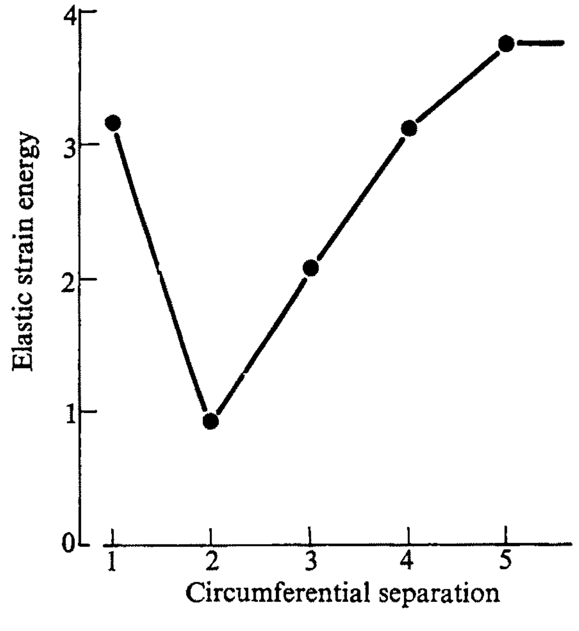

Fig. 4 Strain energy of distortion of a packing involving two columns of rotated units, disposed in various ways. Circumferential separation is counted in numbers of columns; a value of 1 means that the columns are adjacent, and so on. Arbitrary but consistent units of elastic strain energy.

arbitrary number of longitudinal columns around the circumference. We can make the packing contain just 11 columns by insisting that adjacent units make an angle of $360°/11 \simeq 33°$ when viewed along the local axis. This can be done in various ways, all involving inward-facing projections on the units, with interunit connections at the tips. In fact the angular rotation of consecutive units on one of the six-start lattice helices (say) is slightly different for each of the six packings shown in Fig. 2, varying from 34.7° in *a* to 32.4° in *f*. Thus a fine control of this angle, by small changes in conformation of the inward projections, can determine which of the packings is to be built: a wrong packing would not allow simultaneous bonding between the inner and outer structure of the assembly[3].

Design difference in flagellin molecules

I suggest that the flagellin molecules from different strains of *Salmonella* all have nearly the same shape. The observed forms of the filaments shown in Fig. 1 and elsewhere[8,9,12,19,20], can all be understood in terms of small changes in configuration of the unit. These might occur in a given strain in response to a change in the *p*H (compare ref. 7) or as differences between the flagellin molecules of different strains resulting from changes in a few residues on the polypeptide chain.

I have described the essential features of the model; but various other features are not essential. For example, the four outer bonding sites need not form a plane figure; an arbitrary tetragon has essentially the same packing properties. Also, the alternative configurations of the unit need not involve a change within the unit; it is also possible to make the model work by having a bi-stable bonding site at one of the corners of the unit. Anyhow, the design features of the subunit are consistent with what is known about the chemistry and morphology of protein molecules. More details of the three-dimensional geometry of packing, and a closer examination of experimental data[9,12,19,20] will be presented elsewhere.

Dr A. Klug suggested this problem to me, and I thank him for sustained help. I thank Dr S. Asakura and Dr T. Iino for sending advance reports, and Messrs A. A. Barker, E. J. W. Taylor and R. Denston for help in making physical models.

Significance of the angular diameter-redshift relation

Hewish, Readhead and Duffett-Smith[1] have reported that interplanetary scintillation techniques reveal an absence of small-diameter sources at the largest redshifts. They have discussed the cosmological implications of the result using standard, homogeneous Friedmann models of the Universe. Here I point out the important effects on the angular diameter–redshift relation caused by small scale inhomogeneities.

The observational relations in the standard, homogeneous Friedmann models (HFM) have been generalised by Dyer and Roeder[2] to take into account the fact that the Universe may be quite inhomogeneous on the scale of galaxies and clusters of galaxies. The inhomogeneities are put into the models following the method of Schücking[3] and Kantowski[4]. In these inhomogeneous Friedmann models (IFM) the total density may be written

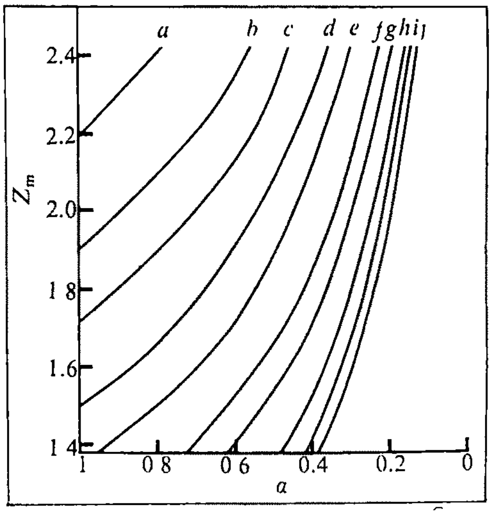
$$\rho = \rho_I + \alpha\rho \qquad (1)$$

where ρ_I denotes the density of inhomogeneities, and α, the homogeneity factor, lies in the range $0 \leq \alpha \leq 1$. If $\alpha = 0$, the model is completely inhomogeneous; if $\alpha = 1$, $\rho_I = 0$ and the model is an HFM. If the lines of sight to distant sources do not pass too close to intervening galaxies, so that shearing of the light beam can be neglected, the distance–redshift relations for the IFM can be expressed as a simple hypergeometric differential equation which gives the solid angle distance, D_s, as a function of the acceleration factor, q_0, the redshift of the source, z, and α. Since the projected area of a source, A, and the solid angle it subtends Ω, are related by

$$A = D_s^2\Omega \qquad (2)$$

it is clear that minimum angular diameter occurs at the redshift for which D_s is a maximum.

Fig. 1 The redshift of minimum angular diameter, Z_m, plotted as a function of α The various Friedmann models specified by letters in the diagram have the following values of q_0:*a*, 0.1, *b*, 0.15; *c*, 0.2; *d*, 0.3; *e*, 0.4; *f*, 0.6; *g*, 0.8; *h*, 1.2; *i*, 1.6; *j*, 2.0.



The redshifts of minimum angular diameter, Z_m, have been calculated as a function of q_0 and α in the zero-shear IFM (Fig. 1). The determination of Z_m is, in itself, not sufficient to determine q_0. Thus, for example, if $Z_m = 1.6$, then $0.25 \leq q_0 \leq 2.0$ corresponds to $1 \geq \alpha \geq 0.3$; and to determine q_0 requires that α be specified. Note that if $\alpha = 0$ there will be no minimum angular diameter regardless of the value of q_0.

The interpretation of further observations of the angular diameter-redshift relation may provide a simple test for the existence of an intergalactic medium, if the acceleration factor can be estimated independently.

Harmonic analysis of the light of DQ Herculis

SEVERAL classes of interacting binary stars, such as the dwarf novae, nova-like variable stars and X-ray stars, present many examples of rapid periodic optical variations. DQ Herculis (nova 1934) is, however, the only nova known to show such variations. They are of low amplitude, generally less than 0.04 mag semi-amplitude, and have a period of 71.065459 s (refs 1–3). We report here a study of the harmonic components of the 71-s periodicity, and show that the results place severe limits on the available models of the variation.

The observations were made in June, August and September, 1973 at the Cassegrain focus of the 2.08-m telescope of the McDonald Observatory using the high speed two-channel photometer developed by Nather and Warner[4]. The data consist of six observing runs totalling 14 4 h of photometry of DQ Herculis; data taken during eclipse were not included. Individual power spectra were computed for each of the observations and these spectra were then averaged together to produce the power spectrum shown in Fig. 1. The frequencies corresponding to the 142-s subharmonic and to the higher harmonics of the 71-s variation are indicated.

The prominent peak corresponds to the 71-s periodicity and is nearly three orders of magnitude above the noise. At the subharmonic frequency, the contribution to the power spectrum is consistent with the surrounding noise level, which is dominated by the optical flickering of DQ Her. The power at the subharmonic frequency is less than the power at the fundamental frequency by a factor of 310 (17.6 in amplitude).

There are no highly significant harmonic components to the 71-s variation. There is, however, evidence for the existence of the first harmonic, since the highest point of the 1,680 points in the power spectrum that lie at frequencies higher than 0.016 Hz is found precisely at the frequency of the first harmonic. After subtraction of noise, it is found that the contribution of this component is less than that of the fundamental by a factor of 600 in power (24 in amplitude). These values correspond to a maximum semi-amplitude for the first harmonic of 0.0017 mag. The remainder of the observed power spectrum has a shape and level consistent with white noise. A conservative upper limit to periodic components in the frequency range of 0.028–0.1 Hz is 0.0014 mag.

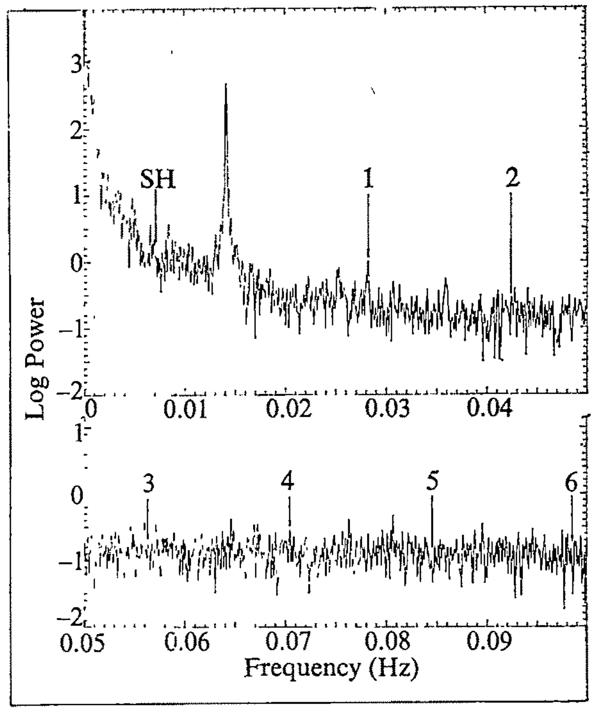

Fig. 1 Log of averaged power of the light of DQ Her showing the harmonic character of the 71-s periodicity. Frequencies corresponding to the 142-s subharmonic (SH) and to the higher harmonics (numbered) are indicated by arrows.

Two major groups of models have been advanced to explain the 71-s variation of DQ Her: non-radial white dwarf pulsations and a rotating white dwarf with a dipole magnetic field[3,5–8]. In general, a rotating white dwarf with a dipole magnetic field should produce a 142-s subharmonic because of physical and geometric asymmetries between the two poles. On the other hand, pulsational models could also require significant contributions to the power at the harmonic frequencies. Our study has shown that the 71-s variation of DQ Her is a sinusoid of remarkable purity, with a small harmonic contribution to the power occurring only at the frequency of the first harmonic. Consequently, no model of the variation can be considered complete unless it is consistent with this purity.

We thank Mr John McGraw for assistance and discussion, and Dr E. L. Robinson for comments and suggestions.

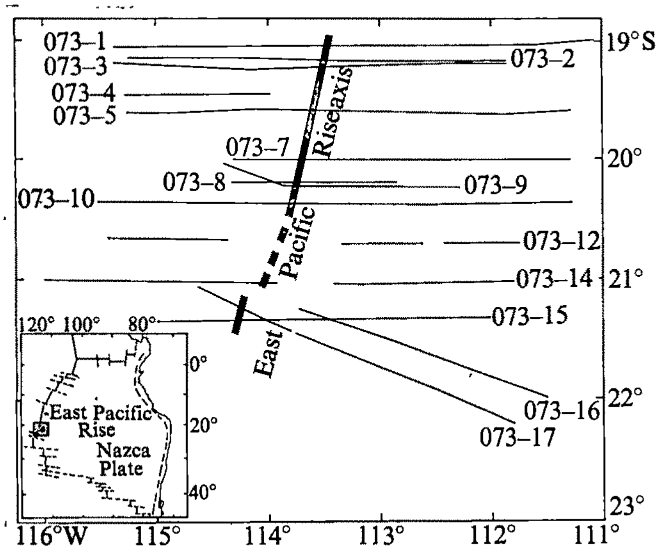
Short-wavelength magnetic anomalies in a region of rapid seafloor spreading

THE main features of the geomagnetic time scale for 0–3 Myr BP are well defined[1–3], but the existence and/or number of short events (polarity intervals lasting less than 50,000 yr) is still under discussion. Interest in correlating these short events with features in marine magnetic profiles has focused on three short-wavelength anomalies: anomaly X[4,5] which appears at approximately 2.3 Myr BP; anomaly W[5–7] at 2.0 Myr BP; and a short-wavelength feature in the centre of the central anomaly[3,6,8,9]. These anomalies appear rarely, and then usually only in profiles from regions of rapid spreading. We present here an analysis of a remarkable new set of data from just such a region. Our results provide evidence of the existence of two, or possibly three, short events in the interval 0–3 Myr BP, and of the existence of a magnetised ridge at the precise centre of seafloor spreading.

Our data consist of 14 profiles from a survey of the East Pacific Rise (EPR) crest, centred at 20°S (Fig. 1), where the total spreading rate is about $161\ \mathrm{mm\ yr^{-1}}$. This survey was completed in the spring of 1973 by the NOAA ship Oceanographer. Navigation was entirely by satellite. Total-field intensity data collected during this survey were reduced to anomaly form[10], and data collected in the vicinity of seamounts or of obvious structural disturbances in the seafloor were discarded. The remaining profiles were projected on to a great circle parallel to the spreading direction—103°—and redigitised to a constant sample interval. These profiles were then transformed to the pole using the method of Blakely and Cox[7], and adjusted to a uniform spreading rate between known[3] magnetic events: the Brunhes–Matuyama reversal boundary at 0.7 Myr BP, the Jaramillo Event centred at 0.92 Myr BP, the Olduvai Event centred at 1.73 Myr BP, and the Matuyama–Gauss reversal boundary at 2.41 Myr BP. Stacking the resulting profiles reduces the random noise in the data set and enhances coherent magnetic anomalies[11,12]. Signals other than those from magnetic reversals, such as from linear topographic features parallel to the rise axis or from intensity fluctuations of the palaeofield[13], would also be enhanced.

Fig. 1 Trackline map of the 20°S area over the East Pacific Rise. Inset, location of survey area.



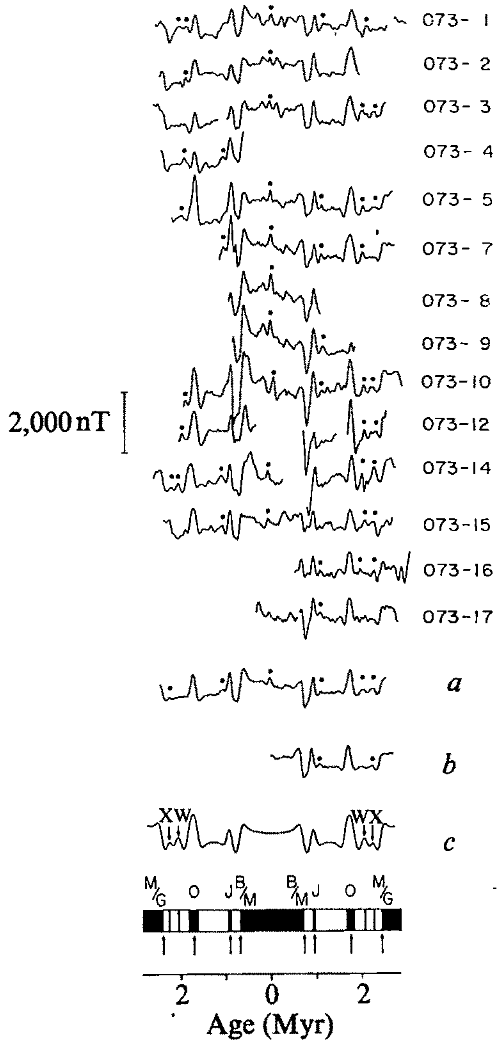


Fig. 2 Individual magnetic anomaly profiles from tracklines shown on Fig. 1. The profiles have been transformed to the pole and adjusted to a uniform spreading rate. *a*, Average of all 14 profiles; *b*, average of profiles after folding in middle; dots, short-wavelength anomalies of controversial origin discussed in text. *c*, Model; arrows, points of 'known' age[3]; black, normal polarity. B/M and M/G Brunhes–Matuyama and Matuyama–Gauss reversal boundaries, respectively; J and O, Jaramillo and Olduvai events, respectively. The model profile (*c*) was calculated from a crustal layer with top and bottom at 3.0 and 3.5 km respectively. Two brief normal polarity events are centred at 2.05 (W) and 2.25 (X) Myr BP.

At 20°S on the EPR, the contribution to the magnetic profile from the abyssal-hill topography is minimal except in the one case discussed here. We have no way, however, of differentiating between anomalies produced by significant palaeointensity fluctuations and anomalies produced by true, short events. For the sake of simplicity we will assume that the short-wavelength anomalies discussed here are the result of brief reversals.

Figure 2 shows the individual profiles and the resulting averages. The computer-generated profile (Fig. 2*c*) was obtained by assuming a horizontal crustal layer with its top and bottom at 3.0 and 3.5 km, respectively. To approximate the imperfection of the crustal recording of geomagnetic reversals, the magnetisation of the layer was convolved with a normal distribution[14,15] thus producing a smooth transition in the polarity of the magnetisation at any reversal boundary. A standard deviation of 4 km for the normal distribution was determined by repeated trials. The time scale used to generate the model is shown at the bottom of Fig. 2. This scale is essentially from Klitgord[3] except that two additional short events are included: the first lasting from 2.03 to 2.06 Myr BP and the second from 2.24 to 2.26 Myr BP.

The anomaly occurring on 83% of our profiles at about 2 Myr BP (Fig. 2) has been reported in other studies of marine magnetic profiles[5-7] and was labelled 'W' by Emilia and Heinrichs[5]. This anomaly probably correlates with the Reunion events, but a controversy exists about the number, age, and duration of these events. A study of volcanic rocks on Reunion Island revealed only one normal polarity event[16], although other evidence suggests that there may be two[1,17] or even three[18] normal polarity events clustered near 2 Myr BP. Some of this other evidence is, however, based in part on an assumed correlation between an apparently bimodal distribution of age polarity data within the span of about 1.95–2.15 Myr BP and the two small marine magnetic anomalies W and X[1,17].

McDougall and Watkins[16] point out that all these dates, because of their nearly overlapping errors, may correspond to the one normal event that they found at Reunion Island and which they dated at 2.02±0.02 Myr BP. They also suggest that this event corresponds to anomaly W, but that anomaly X, dated at 2.3±0.1 Myr BP[5], is significantly older than the event found at Reunion Island[16]. We concur with this suggestion. Unfortunately, because of the large transition width at the reversal boundary and because of inherent limitations on the resolution possible with marine data[11,12], we cannot determine whether anomaly W was produced by more than one event. We can only conclude that it is adequately modelled by a single short event lasting from 2.03 to 2.06 Myr BP.

The anomaly located at about 2.3 Myr BP in Fig. 2 correlates with anomaly X reported in previous marine studies[4-7] and possibly with a short event found in sediments from south-western Ethiopia[18]. Anomaly X appears on 56% of the profiles shown in Fig. 2 and is better represented on the eastern flank of the EPR than on the western flank. We conclude that this anomaly is adequately modelled by a short event lasting from 2.24 to 2.26 Myr BP.

The existence of a brief, normal polarity event about 1.07 Myr ago has been indicated in studies of sediment cores[19,20] and volcanic rocks[21,22] but to our knowledge has not been reported with any certainty[3,6] from marine magnetic profiles A small positive anomaly that would be about 1.1 Myr old appears on 52% of our profiles but is not strikingly evident in the average profiles. Our unpublished data suggest variations in the spreading regime here during Matuyama time and these variations could cause slight offsets among the profiles. Such small-scale variations in spreading rates would preclude precise stacking of this short wavelength anomaly, as with the two anomalies already discussed. The identification of this anomaly as a short event occurring 1.1 Myr ago must, therefore, remain tentative.

The spreading axis of the EPR is commonly denoted by an axial block or peak several kilometres wide and a few hundred metres high[23] In the 20°S survey area there is a small positive magnetic anomaly of 50–100 nT associated with the axial peak found on nearly all crossings of the axis (91% of the profiles in Fig 2). This anomaly is best displayed on lines 5–9 of Fig. 2 and shows up on the average profile. This small anomaly has been recognised in various areas by other authors and two causes have been proposed for it. Emilia and Heinrichs[6] proposed that the Blake reversed polarity event, dated at 0.108–0.114 Myr BP ±10% (ref. 8) caused flanking magnetic lows resulting in a relative, central magnetic high Sclater and Klitgord[9] and Klitgord[3] found a short-wavelength magnetic anomaly associated with the axial peak of the Galapagos spreading centre and related it to an excess of magnetised material within the axial peak.

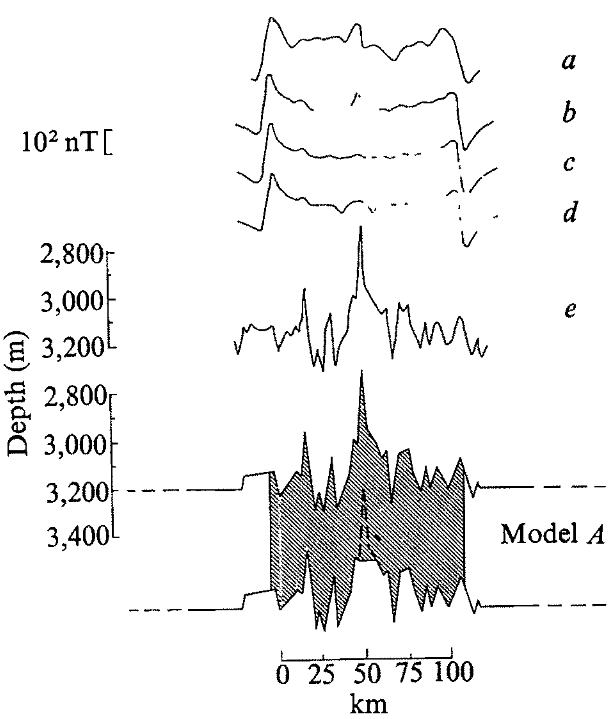

Fig. 3 Observed (*a*) and calculated (*b*–*d*) magnetic anomalies along line 073–5; *b*, assuming central peak atop a magnetised layer 3.0–3.5 km deep; *c*, assuming base of layer faithfully follows the surface; *d*, assuming structure of *c* and including Blake Event; *e*, observed bathymetry. Remanent magnetisation is 0.015 e.m.u. cm^{-3}; shaded regions, normal polarity.

In an attempt to discern which of these causes may be correct, we constructed several magnetic models of the central anomaly of survey line 5. The models all incorporate a magnetised layer 0.5 km thick that conforms to the observed bathymetry and has a uniform intensity of remanent magnetisation of 0 015 e.m.u. cm^{-3} (Fig. 3). In model *A* we have followed the suggestion of Sclater and Klitgord[9] and assumed that the central peak of the EPR rests on top of usual 0 5-km-thick basaltic basement —assumed in this case, to lie at a depth between 3.0 and 3.5 km (Fig. 3). The resulting profile (Fig. 3*b*) provides the best match of all the models which we tested, approximating the short-wavelength anomaly in both amplitude and waveform reasonably well. The second model is similar to the first, except that the central peak is considered to result entirely from block faulting so that the layer is 0.5 km thick throughout The second profile displays essentially no magnetic anomaly over the central topographic peak (Fig. 3*c*) The third model (Fig. 3*d*) is the same as the second but contains the Blake reversed polarity event; the profile calculated from this model has small negative anomalies flanking the central portion, but the overall waveform of the central anomaly is noticeably different from the observed data (Fig. 3*d*).

The close match between the calculated profile (Fig. 3*b*) and the observed profile (Fig 3*a*) suggests that the short-wavelength anomaly associated with the axial peak is the result of a pile of magnetised, extrusive basalt resting on top of a layer of uniform thickness and supports the initial presentation of this idea[9]. Furthermore, our data indicate that the central peak need not be more intensely magnetised than the adjacent material to produce the observed anomaly. As is the case with all modelling efforts, however, we could construct other more complicated models with some combination of the first and third models (Fig. 3*b* and *d*) that would also result in a calculated profile similar to those observed.

In summary, magnetic anomaly data from the EPR at 20°S, where the total crustal accretion rate is 161 mm yr^{-1} reveal several short-wavelength magnetic anomalies. The oldest of these is about 2.25 Myr old and is correlated with the previously reported anomaly X[4,5]. A second small anomaly approximately 2.05 Myr old may be the result of one or two closely spaced Reunion events and is correlated with marine magnetic anomaly W[5]. A brief period of normal polarity about 1.1 Myr ago may be reflected by some individual profiles (Fig. 2) but does not show up well in the average profile. Finally, a short-wavelength anomaly always found in conjunction with the topographic axis of the EPR apparently results from an excess of uniformly magnetised material at the rise axis.

We thank B. H. Erickson who was responsible for the collection and initial processing of the data and Allan Cox for reviewing the manuscript. This work was supported by the US National Science Foundation through the IDOE Nazca Plate Project.

Plate tectonic and palaeomagnetic implications for the age of the Deccan Traps and the magnetic anomaly time scale

IF reconstructions of plate tectonic movement based on magnetic anomaly data are found to be inconsistent with reconstructions based on palaeomagnetic data (see refs 1–3) it may indicate that one or more of the basic assumptions of the plate tectonic model is erroneous; the age or identification of a particular anomaly may be incorrect, the pole positions or sample ages may be unreliable, or there may be an error in assessing plate rigidity. We present an example of inconsistency between the two types of data and explore its implications for the chronology of magnetic reversals during the late Cretaceous and early Tertiary and for the age of the Deccan Traps.

We have previously[4] reconstructed the major plates in the Atlantic and north-eastern Indian Ocean at the time of anomaly 24 (approximately 60 Myr ago according to the magnetic anomaly time scale of Heirtzler et al.[5]). Anomaly 24 is particularly well defined in these oceans, and we estimated that the uncertainty of the relative positions of the plates is about 200 km. Yet when palaeomagnetic poles for Europe and India, implicitly assumed also to be 60 Myr old, are reconstructed according to the positions of anomaly 24 in the Atlantic and Indian Oceans, the pole positions fall short of one another by more than 2,000 km (Fig. 1). It seems reasonable to assume that the plates are rigid, as the only obvious internal deformation has occurred in the East African Rift System and is clearly negligible compared with the discrepancy obtained. Possibly the best sets of palaeomagnetic data are from the North Atlantic Tertiary Volcanic Province and the Deccan Traps, (Table 1, Fig. 1)[6,7]. Thus, the age of either the North Atlantic Tertiary Volcanic Province or the Deccan Traps, or anomaly 24, must be significantly different from 60 Myr.

The dating of the North Atlantic Tertiary Volcanic Province has been particularly thorough. Nearly all of the measured potassium–argon and rubidium–strontium determinations have given ages of 50–65 Myr (Table 1).

The age of the Deccan Traps has been less well determined. Although measured ages range from 40–65 Myr (refs 8–10), argon loss seems to have occurred in some of the samples, and the Deccan Traps could have been extruded entirely between 60 and 65 Myr ago[6,8,10]. Thus, although the few radiometric ages that exist for the Deccan Traps may indicate that both the Traps and the North Atlantic Tertiary Igneous Province were erupted simultaneously the Deccan Traps may, in fact, be a few million years older. At the same time, recent revisions of the magnetic time scale assign to anomaly 24 an age of 56 Myr (ref. 11) or 53 Myr (R. L. Larson, personal communication). Thus, uncertainties in the ages of both the Deccan Traps and anomaly 24 allow some flexibility in reconciling differences of calculated pole positions at the time of anomaly 24. In fact, because of the especially rapid motion of India with respect to both the pole[12] and the surrounding plates[13] during the late Cretaceous and early Tertiary, the ages of both the Deccan Traps and anomaly 24 are critical; an older age for the Deccan Traps or a younger

Fig. 1 Equal area projection of present palaeomagnetic pole positions from the North Atlantic Province (crosses); present Deccan Trap pole positions (open circles); reconstructed pole position of Deccan Traps (in their positions relative to Europe at the time of anomalies 24 and 32, respectively), (closed and dotted circles).

* McElhinny[4] and Bott[42] were used as guides for selecting and combining these data.

age of anomaly 24 will reduce the discrepancy in reconstructed pole positions.

To explore this further we reconstructed the positions of the lithospheric plates with respect to Europe at the time of anomaly 32, with assigned ages of about 75 Myr (ref. 5) and 70.5 Myr (ref. 11). The average pole positions again disagreed, by about 600 km, but in the opposite sense from the disagreement obtained using anomaly 24. The age of the Deccan Traps is apparently less than that of anomaly 32.

Because Europe moved relatively little with respect to the pole during the Tertiary and Cretaceous[6], the North Atlantic Tertiary Province probably moved very little with respect to the pole during the period when anomalies 24 to 32 formed Assuming this, we can use a reconstruction that brings the two sets of palaeomagnetic poles into approximate coincidence to constrain the age of the Deccan Traps or the anomalies. Assuming an approximately constant rate of motion between India and Europe between the times of anomalies 24 and 32, the age of the Deccan Traps can be estimated for various proposed ages of anomalies 24 and 32. Similarly, using given ages of the Deccan Traps and one of these anomalies, the age of the other anomaly can be estimated. Table 2 summarises several combinations of assumed and calculated ages.

Using the time scale of Sclater *et al.*[11], the Deccan Traps are calculated to be only 68 Myr old (line *b*, Table 2). If we accept the age found by Sclater *et al.*[11] for anomaly 32 but Larson's age determination for anomaly 24 (personal communication), then the calculated age for the Deccan Traps is 67 Myr (line *c*, Table 2). Given the uncertainties in all of the ages, reconstructions, and palaeomagnetic poles, 67 or 68 Myr is probably indistinguishable from the measured ages of 60–65 Myr[8–10].

Similarly, assuming that the Deccan Traps are 65 Myr old, then anomaly 32 becomes younger than 70 Myr old (lines *d* and *e*, Table 2). A small change in the assumed age of the Deccan Traps produces a large effect on the age of anomaly 24 (compare lines *b* and *c* with line *g* in Table 2). Because of the uncertainties in the dating of rocks, an accurate determination of the age of anomaly 24 by this method will be difficult. Nevertheless, anomaly 24 must be younger than 60 Myr old.

Table 2 Assumed and estimated ages (Myr) of anomalies 24 and 32 and of the Deccan Traps

	Deccan Traps	Anomaly 24	Anomaly 32
a	72	60 (5)*	75 (5)
b	68	56 (11)	70.5 (11)
c	67	53†	70.5 (11)
d	65 (9)	53†	68
e	65 (9)	56 (11)	66
f	65 (9)	25	75 (5)
g	65 (9)	45	70.5 (11)

* Number in parentheses gives reference; ages not referenced are estimated.

† R. L. Larson, personal communication.

Thus, reconstructions of the Indian and Eurasian plates, using marine magnetic anomalies and differences in the position of palaeomagnetic poles obtained from these plates together place constraints on the ages of both the anomalies and the samples studied palaeomagnetically. These results are consistent both with results of Sclater *et al.*[11] and Larson (personal communication), suggesting that anomaly 24 is younger than suggested by Heirtzler *et al.*[5], and with the idea that the Deccan Traps may be older than measured. The results presented here are also consistent with an age for anomaly 32 younger than that suggested by Heirtzler *et al.*[5]. Plate reconstructions are apparently sufficiently accurate to be used as a laboratory tool for age dating and 'stratigraphic' correlation over large distances.

One of us (J.F.) did this work while on leave from the Centre Océanologique de Bretagne in the Department of Earth and Planetary Sciences of MIT and thanks X. Le Pichon, F. Press, C. Riffaud and J. Mechanism for nucleation and growth of manganese nodules

FERROMANGANESE oxide crusts and concretions cover vast areas of the sea floor[1,2] and the relatively high concentrations of cobalt, nickel and copper in manganese nodules, together with the high population densities of polymetallic nodules on certain sea beds, such as the North Pacific Equatorial Belt[3], mean that these marine sediments are potential ore deposits. A fact that is often overlooked, however, is that in many sedimentary environments most of the manganese and iron does not accumulate in the form of ferromanganese nodules, but instead is distributed throughout the sediment in the form of dispersed microscopic concretions[4]. A fundamental problem in accounting for the origin and distribution of polymetallic nodules is to explain the nucleation and growth of the host ferromanganese oxide phases. We demonstrate here that crystal-structure relationships between host manganese (IV) oxide and iron (III) oxide hydroxide phases control the authigenesis, mineralogy and metal enrichments of manganese nodules.

Observations of the interiors of manganese nodules under the microscope[5], together with electron microprobe analyses[6–8], reveal the intimate associations and oscillatory intergrowths of the manganese- and iron-bearing minerals. Most nodules have formed about a nucleus consisting of pumice, altered basaltic rock or glass, clays, tuffaceous material, or hard parts of organisms (shark teeth, whale bones, globigerina tests, coral or radiolaria tests). Microprobe analyses of the boundaries between the nuclei and ferromanganese oxide layers[9,10] reveal that a hydrated iron oxide phase coats the nucleating agent before the cyclic deposition of Mn oxides plus trace metals and Fe oxyhydroxides occurs. The hydrated iron oxide substrate is probably precipitated at interfaces where the *p*H is locally high as a result of dissolution and hydrolysis of the carbonate, silicate and phosphate anions derived from the nucleating agent[10]. Such evidence for the growth of the Mn oxide phase on a hydrated Fe oxide substrate, together with the intimate association of the ferromanganese oxides across manganese nodules, suggests that crystallographic relationships exist between the constituent Mn and Fe oxide minerals.

Table 1 lists selected manganese (IV) oxide and iron (III) oxide hydroxide minerals for which crystal structure data are available. Todorokite ("10 Å manganite"), the crystal structure of which has not been determined, is also an important constituent of manganese nodules. The acicular habits of todorokite crystallites in terrestrial deposits[11] and in manganese nodules[12] suggest to us that todorokite may have a tunnel structure similar to that of hollandite or psilomelane. Several of the minerals listed in Table 1 are isostructural; thus, each of the pairs goethite and ramsdellite, akaganéite and the hollandite group, and probably $FeOOH.xH_2O$ and δ-MnO_2, have identical crystal structures or contain similar planes of atoms. In such isostructural minerals, oriented intergrowths or epitaxy of one crystalline phase on the other may occur, provided that dissimilarities of lattice parameters or interplanar spacings are not large. Indeed, epitaxial growths of ramsdellite ($a_0 = 4.53$ Å, $b_0 = 9.27$ Å, $c_0 = 2.87$ Å) on goethite ($a_0 = 4.65$ Å, $b_0 = 10.0$ Å, $c_0 = 3.04$ Å) are observed in geodes[13,14]. The mismatch of unit cell dimensions between these two minerals is less than 7%, and seems to be small enough to enable epitaxy between goethite and ramsdellite. The ramsdellite crystal structure[15] contains Mn atoms surrounded by six oxygens at the corners of an octahedron. The $[MnO_6]$ octahedra share edges with adjacent octahedra to form double chains which are cross linked to adjacent double chains by corner sharing of oxygen atoms forming structure with orthorhombic symmetry. In goethite, the double chains of edge-shared $[Fe(O,OH)_6]$ octahedra are further linked by hydrogen bonds[16]. Another way of viewing these two structures is in terms of a hexagonal close-packed oxygen framework in which Mn^{4+} or Fe^{3+} cations are distributed in an ordered array among the octahedral sites. The structure of hydrated ferric oxyhydroxide polymer is believed to contain Fe^{3+} ions in a hexagonal close-packed network[17,18], but the cations are randomly distributed in the octahedral sites with but random order among them. The phase δ-MnO_2 is considered to be a disordered birnessite[19,20] and to contain fragments of the layers of edge-shared $[MnO_6]$ octahedra with small periodicities of stacking along the *c* axis. Thus, δ-MnO_2 also consists of a network of hexagonal close-packed oxygens containing Mn^{4+} ions in the octahedral sites. The structural similarities between δ-MnO_2 and $FeOOH.xH_2O$ make them amenable to epitaxial intergrowths.

We conclude, therefore, that the nucleation and growth of many manganese nodules is initiated by the epitaxial growth of δ-MnO_2 on to the $FeOOH.xH_2O$ substrate coating the nucleating agent. Episodic growths of these two phases on one another lead to the intimate association of Mn and Fe minerals in manganese nodules. Such intergrowths of δ-MnO_2 and $FeOOH\ xH_2O$ inhibit the formation of the ordered layer

Table 1 Isostructural manganese and iron oxide minerals

Manganese (IV) oxides	Manganese (III) oxide hydroxides	Iron (III) oxide hydroxides	Structure type

Hydrocarbons associated with lead–zinc ores at Laisvall, Sweden

BITUMEN and a series of normal alkanes (C_{18} to C_{27}) have been identified in sphalerite from the Laisvall lead–zinc deposit. This is a stratabound lead–zinc ore in Eocambrian sandstone, situated at the eastern border of the Swedish Caledonides. The deposit is an aberrant member of the Mississippi Valley ore class[1]. The main ore minerals are galena and sphalerite, associated with minor amounts of calcite, barite and fluorite. These infill interstices around the sandgrains, often following sedimentary structures[2]. The lead is markedly radiogenic J-type with a $^{206}Pb/^{204}Pb$ ratio of more than 20 (ref. 3). Fluid inclusion studies on the sphalerite give homogenisation temperatures around 150 °C (ref. 4) Laisvall is the largest lead concentration (original resources of about 60 × 10^6 t of 4% Pb) in the 1,000 km long lead- and zinc-rich Caledonian border zone, which includes deposits such as Dorotea and Vassbo.

Samples of the ore and enclosing rocks were taken both from drill cores and hand specimens from the mine itself. Crushed rock samples were washed and shaken three times for 24 h with acetone. The samples were further crushed to less than 63 μm with a pestle and mortar cleaned with acetone. Three grammes of the powder in 5 ml toluene were placed in an ultrasonic bath for 30 min, filtered and evaporated to dryness. The residue was dissolved in 0.10 ml ether–acetone (1: 1), and 3 μl of the solution was injected into a glass capillary column OV-1, 25 m long, in an LKB 2091 gas chromatograph–mass spectrometer–computer system.

The results are listed in Table 1. Total extractable organic matter was variable up to a maximum of 100 p.p m. In most cases the gas chromatogram consisted of a single broad peak, representing a complex mixture of high molecular weight isomers, which can be loosely described as bitumen. In two samples a series of alkanes were identified which made up about 10% of the total extractable material (Fig 1).

The extractable organic matter was concentrated only in those samples containing sphalerite. Samples rich in galena, silica, calcite, fluorite or barite contained low to negligible amounts of extractable material. Furthermore, all sphalerite samples examined were relatively rich in organic matter. We therefore conclude that the organic material is closely associated with the sphalerite and further, that the organic material is partly situated within the abundant[5] fluid inclusions in the sphalerite, although attempts to identify the location of the material (for example by ultraviolet microscopy) have not been successful to date.

Our evidence that this organic material is natural and not an artefact is based on several lines of reasoning. In particular: (1) the enclosing sandstone host rock associated

Table 1 Estimated contents of bitumen and normal alkanes from Laisvall specimens

Specimen no.	Composition	Source	Type	Organic material Estimated total concentration (p.p.m.)	Concentration of normal alkanes (p.p.m.)
L01X	Sphalerite*, calcite, quartz	Nadok orebody	Bitumen	100	Not determined
L02X	Galena*, calcite, quartz	Strand orebody	Bitumen	1	Not determined
L03X	Calcite*, galena, quartz	Lower sandstone (core)	Bitumen	Not detected	Not detected
L04X	Galena*, quartz	Kautsky orebody	Bitumen	1	Not determined
L05X	Galena*, quartz	Nadok orebody	Bitumen	1	Not determined
L06X	Sphalerite*, calcite, quartz	Nadok orebody	Bitumen	100	Not determined
L07X	Barite*, quartz	Lower sandstone (core)	Bitumen	1	Not determined
L08X	Fluorite*, quartz	Lower sandstone (core)	Bitumen	1	Not determined
L09X	Sphalerite*, calcite, silica	Nadok orebody	Bitumen+C_{18}–C_{27} Normal alkanes	~40	4
L11X	Sphalerite*, calcite, silica	Nadok orebody	Bitumen+C_{18}–C_{27} Normal alkanes	~40	4

The estimations were made by comparison with a C_{19} standard. For this reason the estimates of total organic material (as bitumen) are presented as orders of magnitudes, whereas the alkane concentrations are accurate to within ±1 p.p.m.
*Principal constituent.

with these samples, is essentially impermeable with a porosity approaching zero (M.W., unpublished); (2) similar samples, without sphalerite, contain low, possibly background, amounts of organic compounds; (3) both core and hand specimen samples were examined; (4) analyses of possible contaminating substances give either no measurable organic contamination (such as acetone) or different gas chromatograms (such as machine oil and grease); (5) the laboratory preparation was such that the samples could only be contaminated during the final crushing (that is, after acetone-washing of the preliminary crushed samples and before the ultrasonic extraction) and this stage was rigorously controlled; (6) although the possibility of airborne contaminating material dropping into the samples cannot be entirely precluded, the observations that only samples rich in sphalerite suffered this fate and even in these samples different gas chromatograms were obtained, seem to rule out even this possibility.

The identified alkanes in specimens L09X and L11X include the high molecular weight paraffins C_{18} to C_{27} (Fig. 1). A peak observed after C_{27} is consistent with squalene. Work is continuing on this material to identify the origin and authenticity of this observation. The carbon preference index (CPI) is very low, about 0.64. The absence of lower molecular weight alkanes and the low CPI with its even number preference indicates that these substances are not derived directly from biological materials. They must have developed as a result of secondary reactions from the original organic substances. This is not only further evidence against contamination of the samples by modern biological substances, but is also consistent with the age and probable history of the deposit. The sphalerite was formed before the

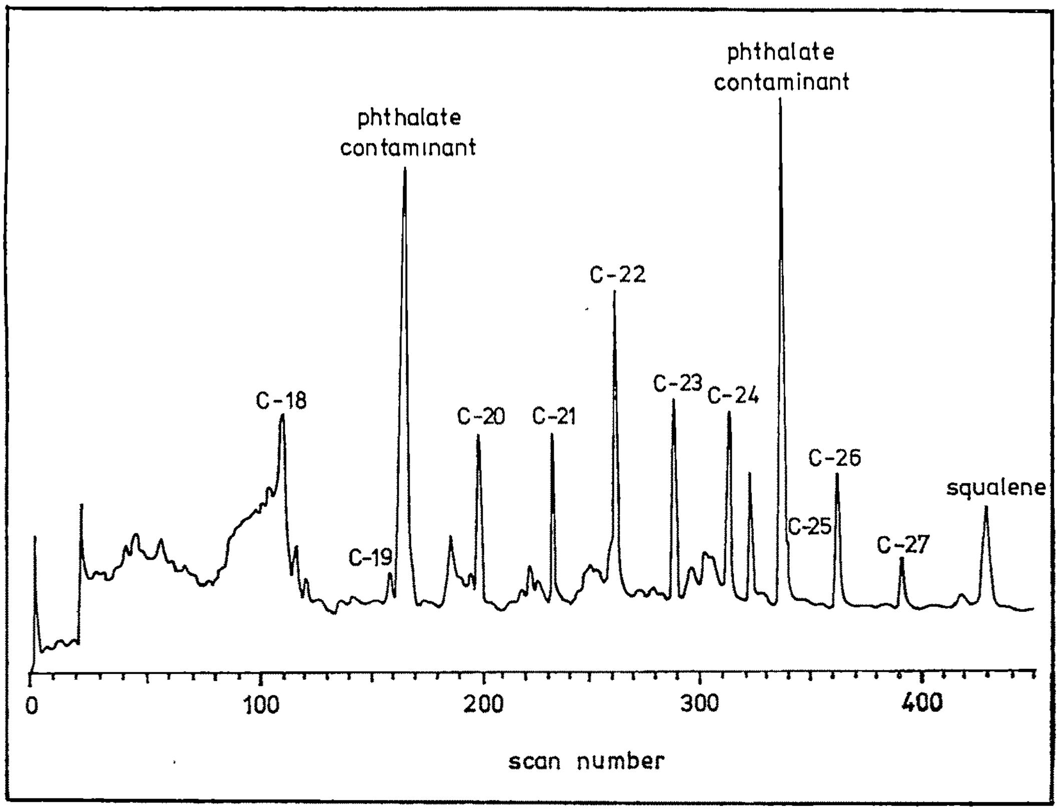

Fig. 1 Gas chromatogram of specimen L09X (sphalerite, calcite and quartz), showing a series of normal alkanes C_{18}–C_{27} and squalene. Glass capillary column OV-1, 25 m long, from 120 °C to 250 °C at 10 °C min^{-1}.

Caledonian orogeny and during or after the Eocambrian sedimentation, a period of about 200 Myr commencing about 600 Myr BP.

It has been proposed on the basis of isotope studies, that the ore forming fluids involved in the formation of Mississippi Valley-type ores were highly saline oilfield brines[1]. The evidence from our study adds further weight to this hypothesis since, in the case of Laisvall, it seems that the solutions contained petroleum-type compounds.

Experimental alteration of chlorites into vermiculites by chemical oxidation

VERMICULITE and chlorite minerals occur commonly in soils where they may be an important source of magnesium and micronutrients. Vermiculite adsorbs and retains potassium and ammonium preferentially, which makes it particularly important in exchange reactions involving these cations. Like micas, chlorites in soils may weather to vermiculites[1,2]. Micas are readily altered to vermiculites in the laboratory by the extraction of potassium. It has not, however, been possible to alter unoxidised, true chlorites to vermiculites by extracting the hydroxide sheets using chemical techniques[3,4] in the laboratory.

I demonstrate here that pure, unoxidised chlorites (IIb polytype) containing an appreciable amount of ferrous iron may be changed to vermiculites in the laboratory using a simple and effective chemical oxidation technique. I show the importance of the oxidation of structural ferrous iron in this alteration process and describe some properties of the vermiculite products.

The alteration technique consists of reacting chlorites in saturated bromine water on a steambath. Samples of 300 mg of 2–5 μm cholite were placed in screw cap, Pyrex vials containing 20 ml of saturated bromine water. The vials were capped tightly and placed in the steambath. After the appropriate time the vials were opened and the bromine boiled off. The samples were separated by centrifugation and then treated twice with sodium dithionite[5] to remove free iron-hydrous and aluminium-hydrous oxides. Portions of the samples were taken before and after the oxidation and dithionite treatments and decomposed in HF (ref. 6). The silicon content was determined colorimetrically[8] and Fe, Al and Mg were determined by atomic absorption spectrophotometry. Ferrous iron was also measured[7]. X-ray diffraction patterns were obtained from specimens basally oriented on glass slides using an instrument with Fe-filtered, Co radiation.

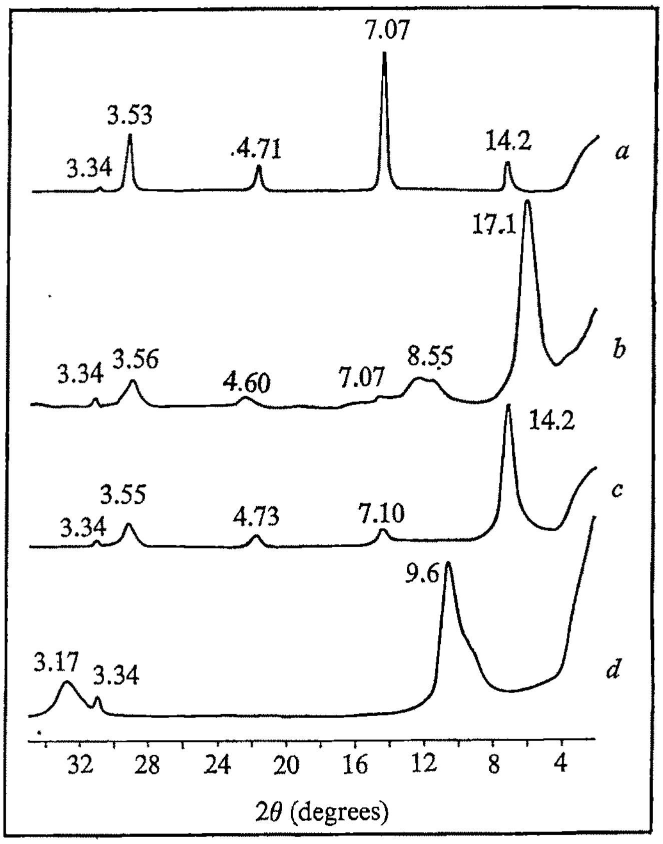

Fig. 1 X-ray diffraction patterns of a high-iron chlorite (diabantite from New Mexico). *a*, Original sample; *b*, *c* and *d*, after 3 weeks' reaction: *b*, saturated with Ca and glycerol; *c*, saturated with Mg and glycerol; *d*, saturated with Ca and heated at 700 °C. Spacings in Å.

Figure 1 shows the transformation of high-iron chlorite — $(Al_{1.57}Fe^{3+}_{0.28}Fe^{2+}_{2.89}Mg_{0.68})(Si_{3.32}Al_{0.68})O_{10}(OH)_8$—into vermiculite after three weeks of reaction. The vermiculite product expands to 17.1 Å when saturated with Ca and glycerol (Fig. 1*b*) and to 14.2 Å when saturated with Mg and glycerol (Fig. 1*c*). This expansion behaviour resembles that of low-charge vermiculites with a cation exchange capacity (CEC) of around 130m equivalent per 100 g. Heating at 700 °C contracts the layers to 9.6 Å but a shoulder at the low-angle side of this peak indicates some (~20%) remaining chlorite layers. The CEC increased from 1.8 to 100.4 meq per 100 g during the reaction.

A low-iron chlorite— $(Al_{1.00}Fe^{3+}_{0.04}Fe^{+2}_{0.39}Mg_{4.72})(Si_{2.62}Al_{1.38})$-$O_{10}(OH)_8$—when treated in the same way as the high-iron chlorite showed very little alteration to vermiculite even after 5 months of reaction (see Fig. 2*a*, *b* and *c*).

The evidence (Figs 1 and 2) suggests that the oxidation of structural ferrous iron is an important mechanism in the alteration of chlorite to vermiculite. This is further brought out by the data in Table 1 which show that the reaction in acid solution without addition of an oxidising agent has little effect on chemical composition and CEC. The X-ray diffraction pattern of this sample also remained identical to that of the original chlorite. In the presence of bromine as an oxidising agent, the composition and CEC change drastically, reflecting the alteration of chlorite to vermiculite. The X-ray diffraction patterns of this sample are shown in Fig. 1*b*, *c* and *d*.

Assuming that the Si-to-Al ratio of the tetrahedral sheets does not change and that 20% of the original chlorite remains unaltered, the formula of the vermiculite portion (80%) in the altered product is $(Al_{0.44}Fe^{3+}_{1.19}Fe^{2+}_{0.40}Mg_{0.15})(Si_{3.32}Al_{0.68})O_{10}(OH)_2\,[Ca_{0.34}]^{0.68+}$. The number of cations (Al, Fe and Mg) in the octahedral sheet is 2.18 which shows that there was a considerable loss of these cations from the octahedral sheets of the mica-like layers during the alteration process. This was also indicated by a decrease in the

Table 1 Partial chemical analysis of original and altered chlorite (diabantite from New Mexico)*

§Ca exchanged with Mg.

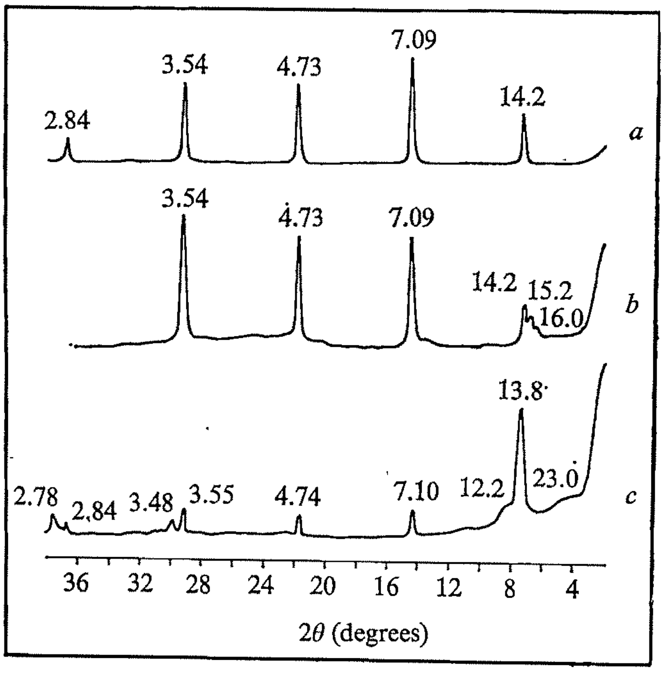
d(060) spacing from 1.557 Å in the original chlorite to 1.537 Å in the altered product, which comprised approximately 20% chlorite layers. Decreases in the *d*(060) spacings because of losses of octahedral cations have also been reported in the oxidation of biotite[8].

It has been proposed previously that selective dissolution of the hydroxide sheet is induced by a structural disturbance of this sheet[9]. During chemical oxidation this structural disturbance is probably caused by the oxidation of ferrous iron and its ejection from the hydroxide sheet.

The results reported here indicate that the oxidation and removal of ferrous iron play an important role in the weathering of chlorites to vermiculites in soils. This was also suggested in a study which showed that one extraction by sodium sulphite or sodium dithionite of a partially oxidised iron chlorite resulted in the formation of a regularly interstratified chlorite-vermiculite[2]. The abundance of chelating agents present in most soils would facilitate the removal of iron from the chlorite structure under less acid conditions than those used in my experiment.

As well as providing clarification about chlorite weathering in soils, the ability to change chlorites to vermiculites in the laboratory provides the opportunity for comparison between the structure and behaviour of chlorite-derived vermiculites and mica-derived vermiculites; it is, however, impossible to do this with soil vermiculites as they are mixed inextricably. Of particular interest in this comparison would be the exchange behaviour with potassium and ammonium, which could well be influenced by the origin of the vermiculites[10].

Fig. 2 X-ray diffraction patterns of a low-iron chlorite (sheridanite from Brewster, New York). *a*, Original sample; *b* and *c*, after 5 months' reactions at *p*H 2.0: *b*, saturated with Ca and glycerol; *c*, saturated with Ca and heated at 700 °C. Spacings in Å.



I thank M Jaakkimainen and N. M. Miles for their technical help and Drs H. Kodama and J. D. Adshead for reviewing the manuscript.

Chemical transport by the Mekong river

Major rivers are important for an understanding of the overall balance of dissolved and particulate matter carried to the ocean[1,2]. Although Livingstone[3] gives a large amount of information on the world surface waters, there is still a lack of data on many important rivers, especially from South-east Asia. These rivers are generally presumed to contribute a great part to the continental and particulate balance[1,3,4], but are poorly documented except for the work of Kobayashi in Thailand[5] and a few analyses performed for the International Association of Scientific Hydrology[6] The Mekong river is one of the biggest in this region[7,8] (Table 1) We have previously studied the hydrology of the Tonle Sap-Mekong system[9] and the influence of the Mekong river on Cambodia Grand Lac water chemistry[10]. Here we deal with analyses performed at Phnom Penh (Fig. 1).

At this station the basin area is 663,000 km^2, 83% of the total drainage area, and mean annual discharge is 14,900 m^3 s^{-1}. Between January 1961 and December 1962, 546 daily samples were taken in which temperature, *p*H and conductivity were measured. The river was at that time affected little by war activities. Once a month a complete water analysis was performed. In this report we set up the mean annual water quality value, compare transport rates

Table 1 Largest rivers of the world according to the water and dissolved salt discharges

†Total ionic transport plus 10% for silica transport.

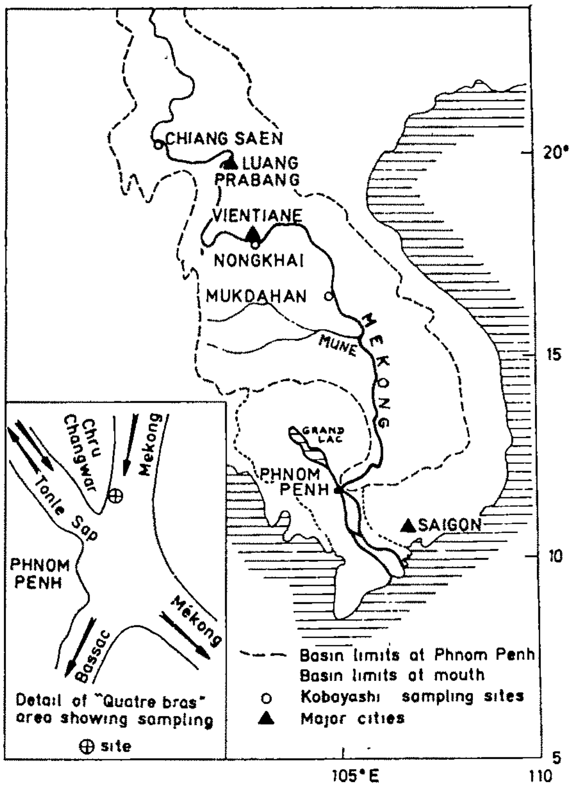

Fig. 1 Map of area.

at Phnom Penh with upstream rates in Thailand recomputed from Kobayashi values and compare chemical erosion in the Mekong basin with those of other Himalayan rivers and determine the importance of South-east Asia for the global dissolved balance.

Mean daily total ionic contents (Σ^{+-} in mg l^{-1}) have been computed on the basis of daily conductivities measured at 25 °C (measured in μmho cm^{-1}) converted into Σ^{+-} according to the relationship

$$\Sigma^{+-} = 0.72 \times \text{conductivity} + 14.3$$

(regression computed for 23 values, $r = 0.97$). The total ionic transport for 1961–62 is $45.5 \times 10^6\ t\ yr^{-1}$. Since the water discharge during this period was very close to the mean annual discharges (14,970 $m^3\ s^{-1}$ as against 14,900 $m^3\ s^{-1}$), this value can be taken as a fair average. Mean major element contents have been computed on the basis of the 24 instantaneous dissolved discharges corresponding to monthly analyses. Total ionic transport given by this less accurate method is $42.6 \times 10^6\ t\ yr^{-1}$ so that annual transport averages for each element were corrected. As dissolved silica is not influencing conductivity, mean SiO_2 transport was not corrected (Table 2). As for the other big rivers[1–3], bicarbonate and calcium are the principal ions carried by the Mekong. The proportion of silica (8.5%) is similar to Livingstone's world mean[3] (11%).

We have recomputed discharge-weighted concentration averages at three Thailand stations studied by Kobayashi[5]: Chieng Saen, Nongkai and Mukdahan (Fig. 1 and Table 1). We used drainage area values and discharge measurements at Mukdahan[11] for estimating monthly discharges at Chieng Saen and Nongkai that were not available to Kobayashi. Transport rates at Chieng Saen are characteristic of the mountainous upper Mekong basin. The total mineral transport rate (86 t $km^{-2}\ yr^{-1}$) is relatively low as compared to other high-relief basins such as the Ucayali river in the Andes[2] (152 t $km^{-2}\ yr^{-1}$), or the Rhone river (France) at mouth (190 t $km^{-2}\ yr^{-1}$). The transport rates are nearly constant along the 1,850-km river course from Chieng Saen to Phnom Penh. The lower Mekong basin is chiefly exposed to monsoon rains and the relief is much more gentle. The

‡Na + K = 2.15 t km^{-2} yr^{-1} from refs 1 and 13, K ≃ Na/3 according to Livingstone[3].

total transport rate in this region can be estimated as 75 t km^{-2} yr^{-1}, still two times the world average (see Table 3). Monsoon action over mid-altitude relief is as erosive as cold climate action over high mountains of the upper basin. The order of transported elements is the same from Chieng Saen to Phnom Penh apart from an increase of Cl^- between Mukdahan and Phnom Penh that can be explained by high Cl^- input between these two stations from Thailand tributaries such as the river Mune[5].

The Mekong dissolved transport rates are compared to Ganges and Brahmaputra rates in Table 3. The Ganges value was computed from three single analyses quoted by Raymahashay[12] at Farakka, by Livingstone[3] at Calcutta and given by G. K. Seth (unpublished). For the Brahmaputra we found only a single reliable analysis at Pandu[12]. So no discharge-weighting has been carried out and these water quality values are inaccurate to the extent of ±50% error for SO_4^{2-} and NO_3^-. General characteristics for these rivers were taken from the UN-ECAFE commission[7,8]. The Brahmaputra transport rates are by far the highest. Total transport is up to 145 t km^{-2} yr^{-1}, the maximum for any such river, and it can be accounted for by the very high relief of this basin (60% is within the Himalaya range compared with only 25% for the Ganges and the Mekong rivers) and by precipitation that is responsible for a high specific discharge, 36 l s^{-1} km^{-2}. Relief is, for Brahmaputra, the main environmental factor that controls dissolved transport; this influence has also been noted for the Amazon basin[3] and for rivers in the Soviet Union[1,13,14]. Ganges transport rates are very similar to the Mekong ones, which may be caused by the similarity of the topographic and climatic features of their basins.

If the transport rates determined at Phnom Penh are extrapolated to the remaining basin area (we assume that there are no major changes arising from rice paddy fields in the Delta), the Mekong carries 1.7% of the global dissolved mineral input to the ocean ($3,600 \times 10^6$ t yr^{-1}, Table 3). This gives it eighth position in the dissolved input 'league' (Table 1). This classification is somewhat different from that of Gibbs[20]. The dissolved matter carried by the 10 'top' rivers is around 33% of the total input to the ocean. We have estimated the dissolved transport rate for mid-relief basins exposed to the monsoon as 75 t km^{-2} yr^{-1}. If this value is taken as a first estimate for South-east Asian rivers still not investigated in detail (Yang Tse Kiang, Pearl, Irrawady, Salween . . .) and for the Indonesia and New Guinea archipelagos rivers, the contribution of South-east Asia from the Ganges to the Yang Tse Kiang to the dissolved discharge to oceans may be more than 30%. It seems necessary, therefore, to study further the geochemical processes in these regions.

A fifteen-year record of biotic metabolism in the Northern Hemisphere

THE health and productivity of the biosphere are essential to man's welfare. Several scientists have speculated that global productivity and/or biomass should be increasing because of such factors as plant fertilisation from industrially derived atmospheric CO_2 enhancement[1,2]. Others have maintained that global primary production and biomass must be decreasing because of pollution effects, such as from acid rain, and forest cutting[3,4]. There are some (rather controversial) tree-ring data that may support this view[5,6]. If one or the other of these trends is true, there would be a shift in the absolute and relative rates of global photosynthesis, respiration and their ratio (the PR ratio). Earlier attempts to ascertain any such trends from long term changes in atmospheric CO_2 concentration have been frustrated by difficulties in distinguishing changes in biospheric retention from changes in the uptake or discharge of other reservoirs, principally the sea and industrial sources[7,8]. We present here a new model for the examination of such trends that we believe avoids such problems by focusing on potential changes in yearly patterns of atmospheric CO_2.

A nearly continuous record of the atmospheric concentration of CO_2 has been maintained for the past 16 yr at Mauna Loa, Hawaii (19.5°N, 155.6°W, 3,400 m altitude[7,9,10]) which is located within the well-mixed tradewind belt. The annual variation in CO_2 content there is 6 p.p.m., roughly representative of the Northern Hemisphere, where the annual variation ranges from about 3 p.p.m. at 10°N to a measured maximum of about 15 p.p.m. at Point Barrow, Alaska (71°N ref. 11). The Mauna Loa data provide the only suitable intensive atmospheric CO_2 record available for the Northern Hemisphere over a sufficient length of time.

These data, which are remarkably smooth and consistent, were obtained with a well calibrated, continuously recording gas analyser, and are corrected for local effects as described by Keeling and coworkers[9,10]. Data are unavailable for only six of the 178 months of this record, and values for these months are estimated from the least square fit of the data to a function of time which included oscillatory and secular terms[7,10].

We, and others[12-14], attribute the seasonal variation in atmospheric CO_2 (about 6 p.p.m.) principally to seasonal changes in net photosynthesis and respiration of the biosphere, although purely physical and chemical criteria, such as annual variations in sea surface temperatures, may contribute slightly. The secular increase (about 0.8 p.p.m. yr^{-1}) is attributed to atmospheric retention of a fraction of the CO_2 produced by industrial processes (principally the combustion of fossil fuels, although the kilning of limestone and other anthropogenic activities contribute a small fraction). Nearly all industrial fuel burning occurs in the Northern Hemisphere.

Our procedure for the analysis of net hemispheric metabolism require the normalisation of the month-by-month CO_2 data by subtracting the industrially derived CO_2. Since month-by-month global industrial fuel combustion numbers are not available, we estimate this by multiplying the global annual rates of anthropogenic CO_2 production by monthly proportions determined from patterns[15-17] in the USA (Fig. 1*b*). These numbers are then corrected for the estimated rate of oceanic CO_2 uptake. The resulting curve, which would be the month-by-month pattern if there were no industrial additions during this time, is plotted in Fig. 1*c*.

We base our oceanic uptake corrections on the work of Broecker, who has estimated that as of 1970 the partitioning of industrial CO_2 among atmospheric and oceanic reservoirs is such that $58 \pm 7\%$ remains in the atmosphere[18]. His calculation is based on a model of the world's oceans which includes a thin, warm, mixed surface layer separated from the cold, deep ocean by a 1 km thick principal thermocline. His model also accounts for enhanced exchange of atmospheric carbon with the deep oceans in the cold, turbulent high latitudes.

Annual terrestrial net photosynthesis for each year is determined by subtracting the trough of each normalised annual curve from the preceding crest. Respiration is determined by subtracting each trough from the following crest. There is no direct precedent for determining net photosynthesis and respiration by this technique, although the method has conceptual forerunners in daily and seasonal net photosynthesis and respiration techniques well developed in the aquatic sciences and used occasionally in forest metabolism studies. The analysis would give us 'net ecosystem production' and 'net ecosystem respiration' as defined by Woodwell and Whittaker[19], although they did not explicitly consider these definitions in terms of annual net growing and non-growing seasons, respectively, as we do.

Therefore we call our measurements 'net hemispheric metabolism,' which includes 'semiannual net photosynthesis' and 'semiannual net respiration.'

A model of hemispheric metabolism that would give the observed curves (Fig. 1*c*) is shown in Fig. 2*a*. In a simulation of global metabolism, using twin sine waves as in Fig. 2*a*, we found our analysis to be sensitive to fairly small increases or decreases in photosynthesis (defined as above) or similar changes in respiration (Fig. 2*b*), but simultaneous unidirectional changes in both photosynthesis and respiration were difficult to discern. But, as discussed below, we would not expect simultaneous unidirectional changes to occur. So we believe this analysis valid for discerning global metabolic trends.

We did not observe any significant trend in either "semiannual net photosynthesis' or 'semiannual net respiration' for the period of this analysis (Fig. 1*d*). Linear regressions of both the photosynthesis (P) and the respiration (R) values were compared to a line of zero slope using Student's *t* tests. Neither regression line was different from the horizontal at the 50% level. Additionally, the slope of the linear regressions for the 15-yr trends in both photosynthesis and respiration, after correction for 51, 58 and 65% atmospheric retention of industrially derived CO_2, never exceeded the standard error of the estimate of the slope for any of these lines.

We do, however, observe an increase in the PR ratio from 1962 through 1968, a change that would produce the dip seen in the calculated data of Fig. 2*c*. Since this change is not explicable by water temperature changes, we assume that this period was relatively favourable to photosynthesis and/or unfavourable to respiration. There was also some slackening in world food

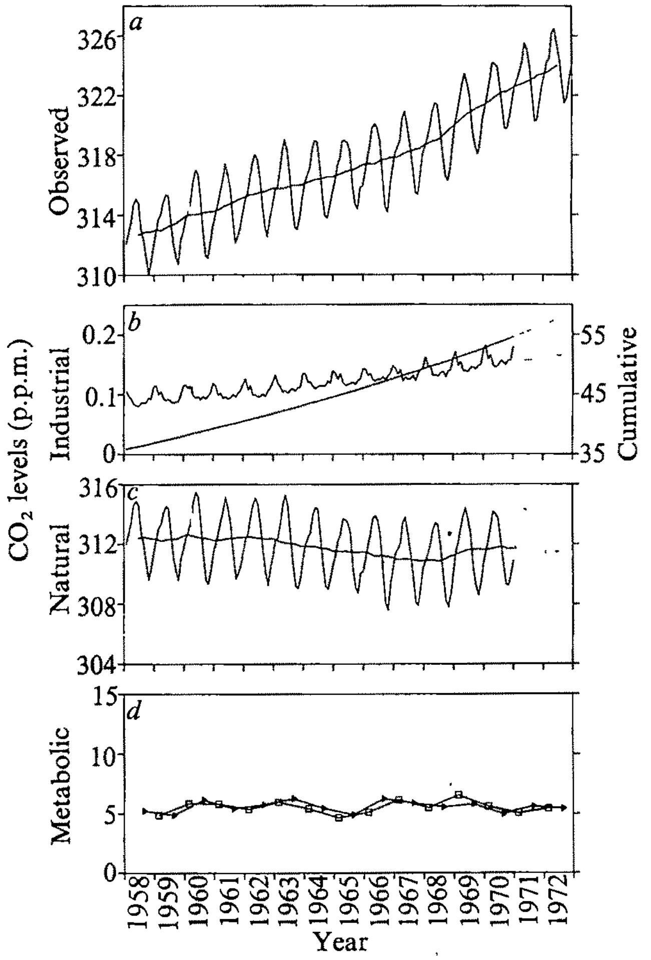

Fig. 1 *a*, Month-by-month variation in the CO_2 concentration of tradewind air at Mauna Loa, Hawaii. The upward sloping smooth curve is normalised for the semiannual fluctuations. *b*, The month-by-month addition of industrial CO_2 to the Northern Hemisphere, along with the cumulative production above the preindustrial level of 293 p.p.m. (ref. 25). The past two years are extrapolated values from the least square fit of data to a third-order polynomial. *c*, The observed CO_2 variation corrected for net industrial additions. *d*, Semiannual net ecosystem production and respiration, determined as the difference between the crests and troughs, in Fig. 2*c*. □, Respiration by difference; △, photosynthesis by difference. Oceanic uptake 42%.

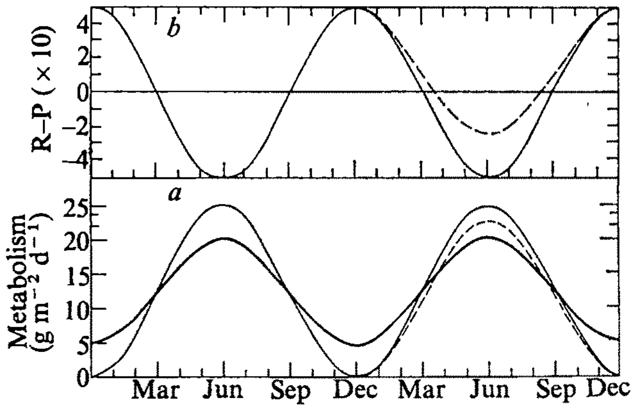

Fig. 2 *a*, A model of terrestrial biospheric metabolism extrapolated from the behaviour of the Brookhaven oak–pine forest[12,26,27]. The difference between 24-h respiration (heavy line) and gross photosynthesis (lighter line) would produce the CO_2 fluctuations plotted as the solid line in Fig. 2*b* or Fig. 1*c*. A 10% reduction in gross photosynthesis would produce the patterns shown as dotted lines in Figs 2*a* and 2*b* superimposed on an upward secular trend as less CO_2 is removed from the air each year.

production during 1964 and 1965, although in general such annual correlations between our estimates of photosynthesis and world food production are not very strong.

There are several possible sources of error in our analysis. The most important include: an incorrect coefficient for the uptake of CO_2 by the sea; an underestimate of the quantity of CO_2 injected into the atmosphere by man's activities; and possible effects of annual or secular trends in oceanic surface temperature. We investigated each in turn by sensitivity analysis of our calculations and/or extensive calculations of work presented previously[13,20-22]. The results of these analyses (available from C.A.S.H.) strengthen our belief in the relative insensitivity of our principal conclusions to possible errors in the data base, and confirm our confidence in the numbers of Keeling, Rotty and Broecker.

Although there are several other factors that could interfere with our analysis that are not well understood at present or not measured, such as annual differences in Hadley cell or other atmospheric circulation patterns, we would expect any secular changes in metabolism to emerge above these, and show as a consistent increase or decrease in one of the lines in Fig. 1*d*, or in their relative positions. For example, a decrease in photosynthesis over a period of years probably would be accompanied by a decrease in the PR ratio, as decompositional processes continued to break down forest biomass. Similarly, if man were cutting forests significantly relative to net photosynthesis, the trees would be oxidised by way of decompositional pathways or burning, and the PR ratio would decrease. This is not consistently the case.

Therefore, we tentatively conclude that, although industrial processes have altered and often degraded many aspects of the biosphere. there is no evidence for changes in the basic pattern of Northern Hemisphere biotic metabolism from 1959 to 1972 within the limits of resolution by this method. Either the biosphere is too big to be affected yet or the potentially adverse effect of such things as acid rain, atmospheric dust loading, urbanisation or replacement of highly productive forests with less productive agriculture is approximately balanced by the stimulatory effects of atmospheric CO_2 enrichment and the increased use of fertilisers in agriculture[3]. In addition, the community compensatory mechanisms elucidated by Botkin and his colleagues[24] in computer simulations of forests would tend to damp potential changes. But if man's impact continues to grow at an exponential rate it will be interesting to follow the gross effects on the biosphere. We suggest our method and its future refinements as one such global index, and recommend that other CO_2 monitoring stations be established at different latitudes and altitudes to facilitate this.

Part of this research was carried out at Brookhaven National Laboratory under the auspices of the US Atomic Energy Commission. The collection of the CO_2 data was performed under the auspices of the National Science Foundation. We thank D. Juers for statistical assistance, R. Houghton for ideas on forest metabolism, C. Cogbill for thoughts on tree-ring analysis, A. Hermann for help with the simulation and H. Lieth, R. H. Whittaker and G. M. Woodwell for critical comments.

Volcanic influence on seawater at Heimaey

VOLCANISM is a contributing factor in marine geochemical processes. It has been shown to contribute to the dissolved silicon in seawater[1], it has also been suggested as the cause of some anomalous fluoride concentrations observed in the sea[2] and it has been seen as a possible source of manganese, iron and other elements found in unusual concentrations in manganese nodules and some deep sea sediments[3,4]. Moreover, it has been suggested that in the geological past volcanism has affected the microfauna of large oceanic areas[5] Here I describe the effect of the recent Heimaey eruption on the waters nearby.

The eruption on Heimaey, the largest of the Westman Islands, started on January 23, 1973, and lasted about five

V1 and V2 samples, small volumes, collected from shore on the harbour side of the advancing lava. Samples 1–24 (Fig. 1) and A1 to A6 were collected from RV Bjarni Saemundsson and from a rubber dinghy by filling 4l polyethylene containers by immersion. The samples were subsequently split into subsamples. Trace metal samples, except mercury, were acidified with redistilled HCl. Mercury samples were collected from the rubber dinghy. Samples A1 to A6 came from the sheltered region off the northern lava front.

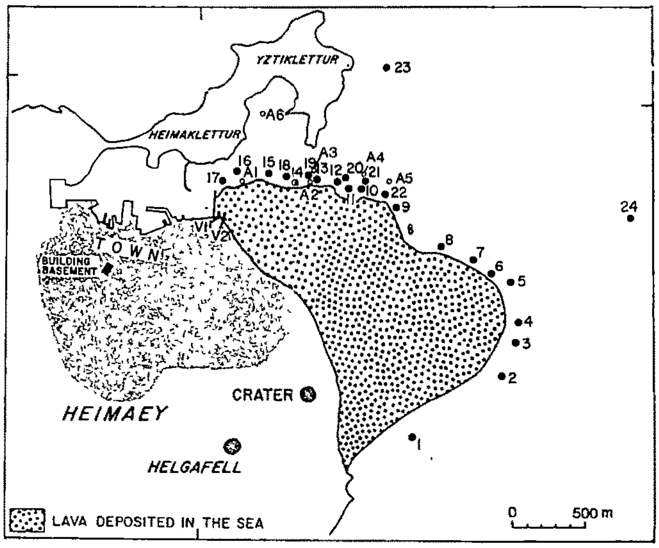
* Cl = S/1.80655.

months, during which a substantial fraction of the volcanics was deposited in the sea[6]. Although the eruption did not occur under the sea it provided an opportunity to observe mobilisation of elements which resulted from the interaction between seawater and volcanics. The material for this study is listed in Table 1. In addition, the extent of the area affected and the normal regional conditions were assessed by examination of samples collected on February 10 during an oceanographic survey of RV Bjarni Saemundsson in the region of the Westman Islands. Temperature and salinity were determined as well as concentrations of fluoride[7], silicate[8], nitrate[8], manganese[9], iron[10], mercury[11], zinc and copper[12].

At Heimaey, the influence of volcanism on the adjacent seawater arose mainly from the viscous lava that advanced spasmodically into the sea. This caused the temperature to rise and also, by evaporation, increased the salinity from the regional range of S=35.0‰ to 35.15‰. On March 9 the warm surface layer that spread out from the lava front was generally thin with a thickness rarely exceeding 1 m. As might be expected this warm surface layer contained a concentration of dissolved silicon considerably in excess of the concentrations of 9–10 μg-atom Si l^{-1} found in the unaffected water.

The solubility and rate of dissolution of silicon in water increases with temperature[13,1] and there is a significant positive correlation (r=0.77) between dissolved silicon and temperature (Table 1) and an even stronger correlation between dissolved silicon and salinity (r=0.91). Since the increased silicon concentration is the result of a dissolution process at the seawater–lava interface, it is of interest to relate the other constituents examined to the concentration of dissolved silicon. All samples with significantly increased dissolved silicon concentrations also had enhanced fluoride/chlorinity ratio and there is a significant correlation (r=0.75) between the two parameters. This confirms that volcanism may considerably increase the fluoride/chlorinity ratio of seawater, although it is clear that such anomalies are unlikely near quiescent volcanoes[14,15]. The fluoride added to seawater in the eruption may either be derived directly

Fig. 1 Seaward position of lava front and sampling locations on March 9, 1973. ▲, Samples collected February 10; ●, samples collected March 9; samples collected March 30.



from the gaseous emanations or be leached from the surface of the lava and tephra. A 100 mg l^{-1} fluoride solution has been obtained by leaching lava ejected on the first day of the Heimaey eruption[16], and the close correlation between dissolved silicon and the fluoride/chlorinity ratio suggests that fluoride has been introduced chiefly by leaching.

The manganese concentration close to the lava front (Table 1) was much greater than the regional background concentration of 2–5 μg l^{-1}; it shows a strong correlation (r=0.94) with dissolved silicon (Fig. 2*a*). Comparison with rock analyses of the new Heimaey lava[16], shows that whereas the elemental ratio by weight of manganese to silicon is 0.011 in the lava, the elements go into seawater solution in the ratio 0.058; this must leave the parent material impoverished in manganese. The distribution pattern of iron around the lava front is altogether different from that observed for manganese and there is no correlation with dissolved silicon or other enriched components. The greatest silicon and manganese concentrations and a very low iron concentration were found in a sample (A2) of seawater that had percolated through a lava front that had been stationary for some time but still remained warm. This suggests that manganese is more readily leached from the lava than iron. The highest iron concentrations on March 9 were associated with brownish patches observed in the sea; this was also the case on March 30. No attempt was made to separate colloidal size particles from samples and in the acidified conditions used for storage, colloidal ferric hydroxides will have redissolved. The distribution of iron suggests that the iron (II) leached from the volcanics was rapidly oxidised and that the colloidal hydroxides have partially separated from the enriched solution, probably by wave action, to create the patchy appearance. A differential precipitation mechanism of this type, that separates iron and manganese, has been anticipated[17] and is thought to be the cause of the distribution of these metals in some deep sea sediments[3,18].

Thermal and redox conditions at the seawater–lava interface are important in the mobilisation of silicon, manganese and iron. For silicon the temperature is of greatest importance, but manganese and iron will only go into solution in reducing conditions. Iron in the fresh Heimaey lava has been shown to be rapidly oxidised in an atmospheric environment[16]. The greatest dissolution of iron and manganese would therefore be expected to occur when the lava front advances into the sea continually exposing new surfaces to attack by seawater. The importance of redox conditions was borne out in a simple experiment where tephra that fell on the RV Bjarni Saemundsson on March 9, 1973, was leached with seawater (1 g per 200 ml) for 15 min using a boiling water bath, the resultant solution gained 41 μg-atom Si l^{-1}, 6 μg Mn l^{-1} and 4 μg Fe l^{-1}, but in a parallel experiment where the solution was 10^{-3} M with respect to hydroxylammonium chloride and slightly reducing, the gains were 41 μg-atom Si l^{-1}, 11 μg Mn l^{-1} and 31 μg Fe l^{-1}.

Table 2 Determinations of mercury in gas samples

Date	Sample	Volume sampled (l)	Mercury* (μg m^{-3})
October 2, 1974	Reykjavík, air†	540	0.007
March 29, 1973	Heimaey town, street air	10	0.44
March 28, 1973	Heimaey town, building basement gas	1.2	3.34
		2.4	3.70
	Fumarole on south-west side of the crater, volcanic gas	1.2	15.0
		1.2	19.0
April 26, 1973	Chimney on lava lake, north east of the crater, volcanic gas	1.0	7.91
		1.0	10.8
		0.5	16.1

*Refers to volume of non-condensing gases.

†Collected by amalgamation on gold. Mercury in all other samples collected by drawing the gas sample with associated condensed water through silicon tube into a gas washing bottle containing 50 ml of 2% potassium permanganate in 25% sulphuric acid.

The zinc concentration was relatively high in many of the samples enriched in silicon; however, there was no significant correlation between the two, which shows that zinc is not brought into solution in proportion to the silicon dissolved. Determinations of copper, cobalt and nickel were also carried out, but only in one instance was an increase above the normal background level observed; this was for sample A2 in which 16 μg Cu l^{-1} was found—about three times the background.

The nitrate concentration decreases near the lava front with an inverse correlation to dissolved silicon, $r=-0.93$ (Fig. 2*b*). This somewhat unexpected finding might be explained as being the result of reduction of nitrate nitrogen to molecular nitrogen (or nitrous oxide) under the reducing conditions at the seawater–lava interface.

The extent of the volcanic influences on the chemistry of seawater was limited to the immediate neighbourhood of the eruption. The water temperature inside the harbour, which was initially 6.5 °C did not rise above 25 °C during the first four days of the eruption. During this time the northward extension of the eruptive fissure was active in the sea[6]. Samples from the oceanographic survey on February 10 revealed anomalies only at three stations that were at a distance between 2.2 and 4.6 km from the eruption. The anomalies were in temperature (up to 10.5 °C), dissolved silicon (26.6 μg-atom l^{-1}), manganese (28 μg l^{-1}) and the fluoride/chlorinity ratio which attained a maximum 7.15×10^{-5}, compared with $(6.79\pm0.07)\times10^{-5}$, for unaffected samples from this survey which is close to the normal oceanic ratio[19] of 6.67×10^{-5}.

The mercury concentrations found near the lava front on March 9 (Table 1) were high for south Icelandic coastal water[11] and the highest concentrations do not correlate with either temperature or dissolved silicon. While collecting these samples it was twice observed that gas bubbles rose to the sea surface off the northern stretch of the lava front. Three weeks later, when the force of the eruption was waning, no gas bubbles were noticed and the samples collected had low mercury concentrations (Table 1). Considering that the seawater mercury may be derived from the rising bubbles of volcanic gas, an effort was made to determine the mercury concentration in the latter. The results summarised in Table 2 show that in comparison with the normal air[20] from Reykjavík, the Heimaey values are high. On April 26 sampling conditions were particularly favourable near the crater and I believe that the gas then sampled represents the unmodified volcanic gas, but I am not certain whether this applies to the fumarole gas. The gas that issued into building basements and lower parts of the town was highly modified, usually containing more than 90% CO_2 (ref. 6). No comparable data are available for the concentrations of mercury in the gaseous emanations of erupting volcanoes, but geothermal mobilisation of the element is well known[21]. It is tempting to use the results in Table 2 to estimate the total amount of mercury ejected into the atmosphere in the eruption. For this purpose it is necessary to assume that the amount of both mercury and water vapour evolved during the eruption was proportional to the amount of solid ejecta, $250\times10^6\,m^3$, or about 600×10^6 t (ref. 6). Second, from solubility data[22], an upper limit of 8% by weight is assumed for the water content of the magma that erupted from a depth of about 20 km (ref. 6). The most representative volcanic gas samples collected during the Heimaey eruption had an average water mole fraction of 63% (Bragi Árnason, personal communication). From the above and the average mercury concentration of 14 $\mu g\ m^{-3}$ in the lava lake and fumarole gases, the upper limit for gaseous mercury emission in the eruption is 7×10^5 g. This is a small quantity in comparison with the anthropogenic atmospheric input which has been estimated at $3\times10^9\ g\ yr^{-1}$ from coal combustion alone[23].

I thank all those who helped in the collection of water and gas samples.

Recognition of the oldest known fossil marsupials from Australia

A PRELIMINARY study has been carried out on fossil remains (unearthed in the British Museum) from a travertine deposit in Tasmania. Regardless of the precise taxonomic assignments ultimately given to this material, the evidence we present that a diverse fauna of diprotodont marsupials existed in Australia in late Oligocene time is of considerable importance. This evidence gives tangible support to the hypothesis that marsupials have been residents of the Australian continent since the early Tertiary at least. The basic differentiation of herbivorous Diprotodonta from Marsupicarnivora (Ride, 1964) very likely took place before the separation of Australia from Antarctica. By late Oligocene time Tasmania was situated near 52°S latitude[1] bathed by warmer seas[2] and the travertine accumulated in an equable warm-temperate to subtropical environment supporting a rich forest vegetation[3-5] the closest living equivalents of which occur in the uplands of New Guinea and New Caledonia. Present-day representatives of some of the fossil marsupials from the travertine still inhabit such tropical environments in northern Australia and New Guinea.

Allport[6] has reported the discovery of fossil mammal remains in the travertine at Geilston Bay (42°50′S, 147°21′E) on the northern shore of the Derwent across the estuary from Hobart, Tasmania. At that time the travertine outcrops at the head of the Bay had been commercially quarried for over 20 years and were well known to naturalists for their rich content of fossil plant and animal remains. Allport noted that the bones we exhibited included forms similar to those of living potoroos and phalangers. Owen's report[7] that "fragments of bones, some teeth, and ungual phalanges of a small kind of *Hypsiprymnus*, with probably also *Perameles* and *Phalangista*" had been identified, led Allport[8] to state that the "bones all proved to belong to existing species", a conclusion that necessitated a considerable revision of the geological history postulated for the site. Allport was forced to explain how the bones of living species could be found many feet below the ground surface and beneath a basalt flow interbedded in travertine associated with a fossil flora having little in common with the present-day flora of Tasmania. Nothing more was written about the bones until Johnston[9] intimated that "it is to be feared they have not been preserved". The Geilston Bay collection and its whereabouts thus passed into obscurity primarily because of the belief that it represented only a Recent fauna.

Mahoney, conducting a search for bibliographic materials relating to the Australian fossil mammals in the British Museum (Natural History), located the Allport collection in the museum's holdings. Preliminary examination of the fragmentary remains leaves no doubt that the fossils represent new taxa of marsupials. An assemblage of Tertiary age is strongly indicated, and this recognition has led us to re-examine the geology of the Geilston Travertine and associated basalts to determine the age of the fossiliferous deposit.

The bones were found[6] in an "arenaceous clay, containing coarse grit, and a few slightly rounded pebbles" interbedded with the travertine. Matrix still adhering to some specimens confirms this description of the containing rocks. Allport also indicated that work west of the quarry towards the River Derwent had exposed the east dipping contact of the travertine with the overlying basalt. Several geologists have observed the quarry working face, for travertine was produced from the site at least until 1924. Johnston[10] recorded (in descending order) the following composite section in the quarry and adjacent area: 1.5 m of weathered basalt overlying 1.2 m of silicified ostracod limestone, 1.8–2.4 m of yellow and brown mottled calcareous clay with marl lenses from which he alleged the marsupial remains were obtained, 3.1–3.6 m of travertine with plants and snails and 1.8 m or more of brown clay extending below the level of the estuary. A similar section, but without the basalt, was recorded by Krause[11] in his map of part of the Hobart area and Nye[12] reported "thin layers of limestone occur above the basalt" as well as beneath. Moore[13] gives one of the last direct reports on the abandoned quarry and maps two outcrops of basalt along the south side of Geilston Bay, both of which are shown to extend to the edge of the estuary. Between these outcrops Moore's map shows "hornblende tuff", but this is a printing error, for the outcrops in that position are the Geilston Travertine (W. R. Moore, personal communication). Our observations show that the westernmost basalt outcrop overlaps Permian (Malbina) siltstone at a higher elevation than shown on Moore's map, and that it extended beyond the head of the bay to become continuous with the eastern outcrop, and to thus overlap the Geilston Travertine. These relationships seem to indicate that the basalt partially filled a narrow canyon containing a spring which had built up a considerable travertine apron before being buried by basalt and which subsequently continued to deposit travertine above the basalt. The combined observations of many geologists extending over 100 yr clearly indicates that the Geilston Travertine is mostly sub-basaltic (that containing the marsupial bones certainly so) and that travertine deposition was halted for a time by the basalt incursion and it is thus reasonably contemporaneous with the basalt. These conclusions had been anticipated[14].

It is now impossible (because of development) to secure a sample of the basalt at the travertine quarry. Therefore samples of the basalt from the western outcrop were collected for possible isotopic dating, and the least altered of these (Tasmanian Museum No. 22241; ANU No. 74-98) was measured by the K–Ar method. The sample was collected approximately 100 m from the head of Geilston Bay at sea level on the southern shore. This basalt contains about 5% mainly fresh olivine phenocrysts set in a well-crystallised fine-grained groundmass of plagioclase, clinopyroxene, olivine and iron oxide, together with 5% green mineraloid and minor calcite. The plagioclase shows evidence of some low temperature deuteric alteration. The basalt yielded an apparent age of 22.4 ± 0.5 Myr ($K=0.765\%$; rad. $^{40}Ar=3.07\times10^{-11}$ mol g^{-1}; 100 rad. ^{40}Ar/total $^{40}Ar=90.0$; $\lambda_e=0.585\times10^{-10}$ yr^{-1}; $\lambda_\beta=4.72\times10^{-10}$ yr^{-1}; $^{40}K/K=1.19\times10^{-2}$ atom %). Because of the somewhat altered nature of the basalt the measured age must be regarded as a minimum estimate for the time of crystallisation because of the possibility of some diffusive loss of radiogenic argon. The measured age approximates closely the estimated age of 22.5 Myr for the Oligocene–Miocene boundary[15], thus the Geilston Travertine underlying the basalt is considered to be late Oligocene or older.

The oldest previously known Australian marsupial *Wynyardia bassiana* was also from Tasmania at Fossil Bluff on the north-west coast where a skeleton was recovered from the Fossil Bluff Sandstone of early Longfordian age[16]. Recent radiometric calibration of the Longfordian Stage from the northern side of the Bass Basin in Victoria suggests that its base is approximately 21.4 Myr (ref. 17) and thus *Wynyardia* is of early Miocene age.

At least three mammalian taxa can be discerned among the very fragmentary remains from the Geilston Travertine. All identifiable remains seem referable to the Order Diprotodonta (Owen, 1866) and none can be relegated to the Peramelidae (Waterhouse, 1838) as Owen had stated. The largest form is represented by a fragment of a left maxillary with well worn dentition including part of M^1 and M^2–M^4 complete (BMNH 40157, length M^2–M^4 25.1 mm). This dentition resembles the Miocene palorchestine diprotodontid *Ngapakaldia* (Stirton, 1967) closely enough to encourage tentative assignment to that subfamily. It is about 60% of the size of *N. tedfordi* (Stirton, 1967) from the Ngapakaldi Fauna of the Lake Eyre Basin. More abundantly represented is a second and smaller form that is postulated on the basis of tentatively associated edentulous jaw fragments, an unworn left M^1 (BMNH 32000, length 4.3 mm) and left M^2 or M^3 (BMNH 32001, length 4.2 mm), and other tooth and skeletal fragments. In mandibular dental formula and morphology these remains resemble those of the smaller species of *Phalanger* (Storr, 1780) and although other features bar assignment to that genus, reference to the Family Phalangeridae (Thomas, 1885) seems likely. A third form is indicated by a lower incisor which agrees best with those of living Burramyidae (Broom, 1898).

We thank J. A. Mahoney (University of Sydney) and the trustees of the British Museum (Natural History) for permission to report on the Geilston fauna, and W. R. Moore for data on the geology of the site. This research was supported in part by a NSF grant to R.H.T.

Use of a self-made sound baffle by a tree cricket

FIELD observations and sound recordings of several South African species of Oecanthidae were carried out during the summer and autumn of 1973–74 to augment studies of the acoustic behaviour of the tree cricket performed abroad[1–6]. We report that *Oecanthus burmeisteri* uses a leaf as a sound baffle to increase the intensity of its calling song by pressing its tegmina against the edges of a pear-shaped hole gnawed into the leaf.. At least two more South African chirping *Oecanthus* species use a leaf baffle just as efficiently as *O. burmeisteri.*

The calling song of the male *Oecanthus burmeisteri* Saussure consists of regular chirps repeated for hours on end during the summer, from dusk to about 2 h past midnight. The chirping sound is actually produced by a frictional mechanism involving the elytra. The right front wing bears the stridulatory file, a row of regularly spaced 'teeth'. A sclerotised edge of the left wing serves as the scraper. When the file and scraper are rapidly rubbed together a sound is produced. Chirps recur at about 2 s intervals, each complete chirp lasting for 300 ms and consisting of ten bursts, each burst being made up of an almost sinusoidal oscillation at 2,000 Hz. This frequency is near the lower end of the scale for *Oecanthus* calls.

Interest in the sound production of the Oecanthidae was aroused by the first *O. burmeisteri* male found singing on a small sunflower leaf on December 21, 1973 in Pretoria The insect producing the soft, insistent call was found on the underside of a leaf sitting in a small pear-shaped hole which it had gnawed and which differed from the irregularly shaped feeding holes The foremost part of its body

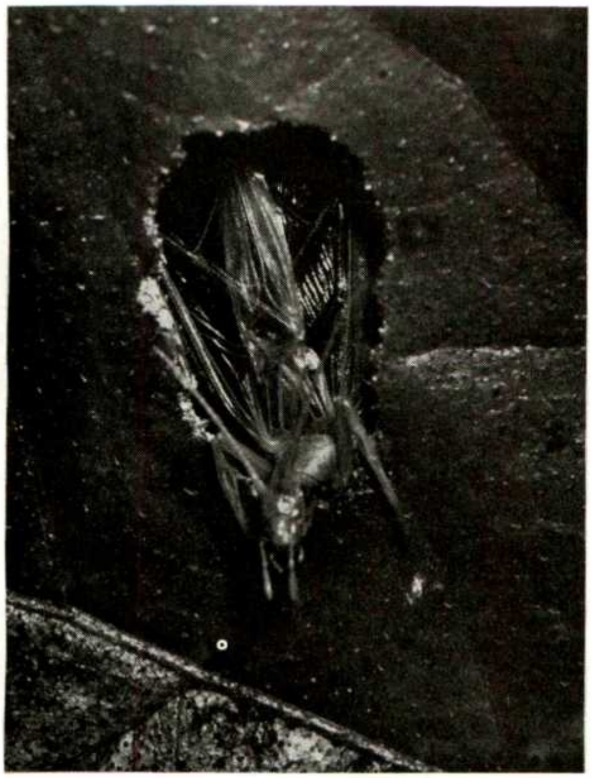

Fig. 1 Leaf used as a baffle. Wings pressed tightly against the edges of the hole gnawed by the insect.

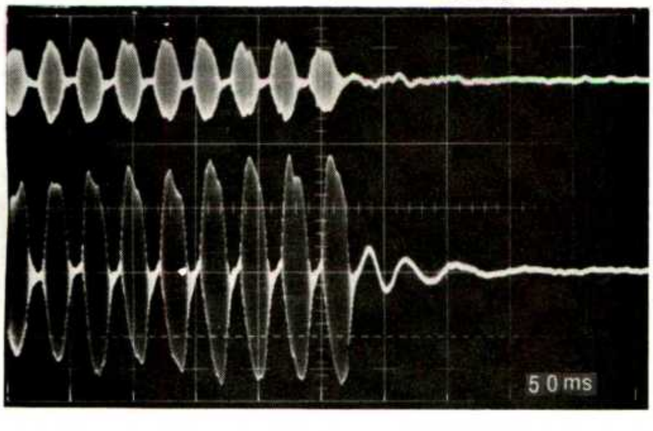
and front legs protruded on to the upper leaf surface. During stridulation the elytra (or modified front wings) were raised at right angles and their lateral and apical margins were tightly pressed against the leaf surface surrounding the hole. Almost all male singers were sitting in similar positions.

Remembering that, according to Bennet-Clark[7], the mole cricket forms its burrow into the shape of twin exponential horns to increase its sound intensity, it occurred to us that *O. burmeisteri* may be fashioning and using a leaf for the same purpose. A microphone was therefore placed at a fixed position 15 cm from a male and a recording made first of the insect's song when sitting in front of the hole and then immediately afterwards when this individual was sitting inside the hole with its wings pressed against the leaf (Fig. 1). The orientation of the insect with respect to the microphone was the same in both cases. Consequently there was no possibility that directional effects in the sound radiation pattern, as suggested by Bennet-Clark[8], were present. Gain settings of the recording and reproducing systems were held constant.

Fig. 2 Oscillograms of two chirps of *Oecanthus burmeisteri*; upper trace, without baffle; lower trace, using baffle.



Oscillograms of the results obtained (Fig. 2) show that the sound amplitude is far greater in the second case, thus proving the effectiveness of the leaf baffle in amplifying the sound produced by stridulation. At the beginning of the chirp shown the amplitude ratio is 2.5 but rises to 3.5 for the final tone burst. This build-up is probably caused by the cricket steadily increasing the pressure of its elytra against the leaf, thus gradually increasing the effectiveness of the baffle.

A vibrating body, small compared with the wavelength of the sound it produces, is a poor sound radiator because a compression wave created on one side largely cancels the simultaneous rarefaction wave on the opposite side. For this reason Bennet-Clark[8] as well as Michelsen and Nocke[9] concluded that insects producing low frequency calls could increase their sound intensity by using a baffle. They show that as the size of a baffle placed around a sound source is gradually increased so the radiated sound intensity increases, reaching a maximum when the baffle diameter is approximately half the wavelength of the sound concerned. This is a well known acoustic phenomenon[10].

The wavelength of the 2,000 Hz note of *O. burmeisteri* is 170 mm, the diameter of its sound-producing membrane approximately 3.2 mm—only one-fiftieth of a wavelength. Consequently the membrane is a poor sound radiator. The sizes of the leaves used ranged from 70×80 to 170×300 mm, so even the smallest formed an efficient baffle. The hole, usually near the centre of the leaf where it would be most effective, averaged 8×14 mm in size thus ensuring a good fit for the elytra.

Measuring the relative importance of different pollinators to plants

THE development of a predictive theory of pollinator–plant coevolution requires a means of assessing and comparing quantitatively the costs and benefits of different pollinator foraging strategies and plant flowering strategies. Although there are quantitative data for pollinator strategies[1–3], the relative benefits to the plant of alternative pollinators, in terms of pollen transferred, ovules fertilised, and seeds set, have never been quantified for field conditions. Likewise, reference to the most effective pollinator[4] of a plant species is often based on estimates of the abundance of alternative pollinators. Demonstrations that various pollinators can cause seed set in caged plants[5] and that pollinators transfer pollen in different amounts[6,7] are difficult to relate to natural conditions. We have developed a quantitative approach for comparing the relative importance of alternative pollinators in terms of the quantity, level of out-crossing and efficiency of pollen transferred. We have used this approach to investigate the pollination of evening primroses, *Oenothera fruticosa* L. (Onagraceae), by two principal pollinators, European honey bees, *Apis mellifera* L., and soldier beetles, *Chauliognathus marginatus* Fab.

The quantity of pollen transferred per unit time can be calculated as the mean number of grains transferred to the stigma of a flower per pollinator visit multiplied by the mean number of flowers visited per unit time. Likewise, the quantity of pollen transferred per unit time by one species of pollinator can be calculated as the number of foraging individuals of that species multiplied by the quantity of pollen transferred by an individual per unit time.

Pollen transferred within a plant produces no seeds in self-incompatible species, and may result in lower quality seeds in self-compatible species. The proportion of pollen grains transferred that are out-cross (between plant) pollen (P) can be calculated considering the number of flowers visited per plant (N)[8,9], the number of pollen grains transferred per visit (G), and the number of grains on the body of the pollinator (B):

$$P = (1/N)\sum_{i=1}^{N}(1-G/B)^{N-1} \quad (1)$$

We assume that the pollen load on the pollinator is in dynamic equilibrium and that an equal number of pollen grains is exchanged on each visit.

The relative importance of soldier beetles and honey bees in the pollination of *O. fruticosa*, a self-incompatible plant, was investigated in a moist field north of Durham during May and June 1973 and 1974. The yellow flowers with eight stamens and a prominent, four-lobed stigma, remain open for 1 or 2 d (between approximately 0900 and 1700). Bees visited the flowers primarily for nectar, while beetles foraged for both nectar and pollen. Bees averaged 4.0 s per flower and beetles averaged 27.6 s per flower, during 341 and 54 visits, respectively. Over this time, the bees visited 4.9 flowers per plant whereas the beetles visited 2.6 flowers per plant. Bees and beetles were caught as they left the flowers and pollen was removed from them in agitated alcohol rinses. The bees averaged 1,100 pollen grains on their bodies ($n = 12$; s.d. $= 494$; range 436–1730) while the beetles averaged 217 ($n = 8$; s.d. $= 190$; range 19–570).

To estimate the pollen grains transferred per visit, virgin flowers were presented to the foraging bees and beetles and the grains on the stigma were counted after one visit. Bees transferred a mean of 193 pollen grains per visit ($n = 24$; s.d. $= 135$; range 9–548), while beetles transferred 114 grains per visit. The latter figure is based on only two observations, but for illustrative purposes the data for beetle pollen transfer will be used in further calculations. Individual bees and beetles transferred 174,000 and 14,900 pollen grains per hour, respectively. If the number of foraging bees and beetles is equal, then the former account for 92.1% of all pollen transferred. This estimate is biased in favour of beetles, as there seemed to be many more bees than beetles in any given area of the *Oenothera* population.

The level of out-crossing effected by the pollinators can be calculated from equation (1). For bees carrying 1,100 pollen grains, transferring 193 grains per visit, and visiting 4.9 flowers per plant, 71.2% of the pollen transferred would be out-cross pollen. For beetles carrying 217 grains, transferring 114 grains per visit, and visiting 2.6 flowers per plant, 63.5% of the pollen transferred would be out-cross pollen. Thus, bees would account for 92.9% of the out-cross pollen being transferred.

The energetic efficiency of pollen transfer was contrasted for the two pollinators on the basis of quantity of pollen transferred per calorie of nectar available. *O. fruticosa* flowers produced 0.3 µl of nectar at 45.3% sucrose equivalence or 0.52 calories per flower averaged across the population. Assuming that the pollinator removed all nectar from the flower during a visit, bees transferred 373 pollen grains per calorie of nectar produced, and the beetles 220 pollen grains per calorie. With a mean of 143 ovules produced per plant and a seed set of 54% averaged across the population, nectar production can be expressed as 0.036 calories of nectar per ovule produced or 0.067 calories per seed set. Individual bees transferred more pollen grains per unit time, more efficiently, than the beetles and a greater percentage of those pollen grains was out-cross pollen resulting in higher seed set. On the other hand, beetles may be able to forage profitably on smaller plants or poorer quality flowers because of their low level of activity and presumed lower caloric requirements. In sparse populations of *O. fruticosa* or on days when only a few flowers are open, beetles may increase in their relative importance as pollinators.

Differences in the pollination service provided by various pollinators may be an important selective force operating on plant populations. If pollinator service limits seed set, genotypes that possess flowers more attractive to a certain pollinator or a more efficient pollen attaching or removing mechanism will produce more seeds[10]. Alternatively, if pollinators are abundant, genotypes which receive the same pollinator service per flower while producing less pollinator attractants per flower, may be able to produce more flowers and set more seeds. Evolutionary shifts in floral morphology, colour and timing of flower production[11] are almost certainly associated with a new pollinator providing a higher quantity of pollen transfer or a higher level of out-crossing than a previous pollinator. The new pollinator may also provide the same level of pollen transfer but require less food during foraging. The honey bee as an introduced pollinator may impose a high selection pressure on *O. fruticosa* in populations where it is the primary and most efficient pollinator. Although insufficient time may have elapsed from introduction for the honey bee to have had an impact as a selective force on the particular set of characters that *O. fruticosa* now possesses, a responsive shift in floral characters may be predicted in the future. Only by measuring both the importance of pollinators to plants and the importance of plants to the pollinators, can the reciprocal selective forces which operate at the animal–plant interface be determined.

^{14}C-ethylene incorporation and metabolism in pea seedlings

ETHYLENE is now generally accepted as an important, integral part of the natural hormonal complement of many plants[1]. Although the morphological, physiological and biochemical effects of the gas are well known, surprisingly little is known about its metabolism. There is no agreement as to whether or not ethylene is even incorporated into plant tissues. Several reports[2-4] of work using ^{14}C or ^{3}H-labelled ethylene indicate that it is not incorporated whereas others[5-10] suggest that a small, yet significant amount is fixed and metabolised. The criticism[1,11,12] of these papers, on the basis that adequate precautions were not taken to insure that the label fixed and metabolised was derived from ethylene, has led Abeles[1] to conclude that ethylene incorporation is probably not a prerequisite for ethylene action. A second major criticism of these studies is that no precautions were taken to exclude microbial contamination which could have accounted for the observed metabolism. Here, I report the results of experiments in which ^{14}C-labelled ethylene of very high purity was applied to etiolated pea seedlings under aseptic conditions to study its possible incorporation and metabolism. They reveal a previously unrecognised active metabolic system in pea which converts $^{14}C_2H_4$ to $^{14}CO_2$, as well as to unidentified tissue components.

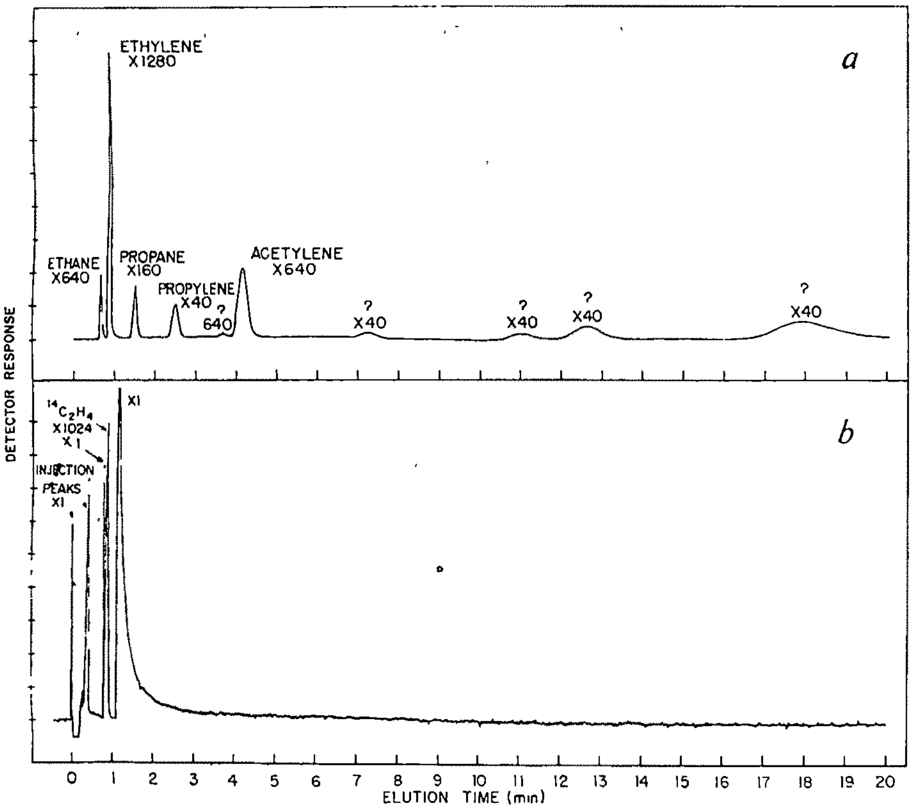

Fig. 1 Gas chromatograms of $^{14}C_2H_4$ (specific activity 53.0 mCi mmol^{-1}) before (*a*) and after (*b*) purification. Samples analysed on an activated alumina column using standard flame ionisation gas chromatography. This system could detect 6 parts per 10^9 C_2H_4 in a 1 cm^3 sample. At least nine major impurities were detected in the purchased $^{14}C_2H_4$ before purification whereas none was present in the twice purified material. The two $^{14}C_2H_4$ peaks at retention times of 0.80 and 0.85 min are the result of attenuating the $^{14}C_2H_4$ peak at 0.80 min from maximum sensitivity (×1) to ×1,024 to prevent it from going off scale. The apparent peak at 1.1 min is the result of increasing the sensitivity back to ×1 and represents the tailing of the $^{14}C_2H_4$ peak at this higher sensitivity.

Uniformly labelled $^{14}C_2H_4$ (reported radiochemical purity 98%, 22 or 53 mCi mmol^{-1}) was purified twice by gas chromatography (GC) and first separated on a silver nitrate ethylene glycol-coated Gas Chrom R column[11] at 0 °C. The ethylene fraction was collected and further purified using the same technique on a Poropak T column. Figure 1 illustrates the effectiveness of this purification scheme. No impurities were detected in the purified $^{14}C_2H_4$ even at maximum GC sensitivity.

With a gas-tight syringe fitted with a Millipore filter (0.22 μm), the desired amount of purified $^{14}C_2H_4$ was immediately injected into flasks containing three aseptically grown etiolated pea seedlings (0–5 d old). Each flask contained 3 ml sterile deionised water and 1 ml 1.5 N NaOH (electrolytic pellets) in the centre well. The flasks were placed on a shaker for 24 h in the dark at 27 °C. All operations were conducted using a 'safe' green light. Following incubation the ethylene concentration in each flask was determined and the seedlings plus the 3 ml of water were transferred aseptically to a mortar and homogenised. An aliquot (0.1 ml), diluted 20-fold, was plated on each of four different culture media to check for microbial contamination. Petri dishes were incubated at 30 °C for 1 week and the data from any sample showing contamination were not used. The remaining homogenised tissue was lyophilised, weighed, resuspended in water and counted by liquid scintillation in Aquasol (New England Nuclear). The NaOH was removed and 0.8 ml was counted in a similar manner. All data were corrected for counting efficiency and sample quenching by the internal standard method using ^{14}C-hexadecane.

A highly significant and readily detectable amount of $^{14}C_2H_4$ incorporation and conversion to $^{14}CO_2$ was observed in pea seedlings when treated with 15 μl l^{-1} of $^{14}C_2H_4$ (Fig. 2*a*). During the first 20 h after imbibition, the amount of $^{14}C_2H_4$ incorporated and converted to $^{14}CO_2$ by the pea seedlings was relatively small, amounting to 1.1 and 0.6 d.p.m. per mg dry weight per 20 h, respectively. During day 2, however, tissue incorporation and $^{14}CO_2$ release rapidly increased reaching a peak on day 3 of 12 and 33 d.p.m. per mg dry weight per 24 h, respectively, and then gradually declining during days 4 and 5. A peak of natural ethylene production preceded the peak in ethylene metabolism by approximately 24 h (Fig. 2*b*) and like ethylene metabolism gradually declined thereafter. In contrast to ethylene production and metabolism, respiratory CO_2 production remained relatively constant after reaching a peak of 17 μl per mg dry weight per 24 h on day 4 (Fig. 2*c*).

Considering the rigorous purification procedures used, it was highly unlikely that an impurity in the labelled ethylene may have still accounted for these results. Nevertheless, additional evidence was sought to further eliminate this possibility. The purified material was first pretreated with NaOH to remove possible acidic impurities or with $Hg(ClO_4)_2$, $KMnO_4$ or Br_2–H_2O to remove ethylene before exposure to pea seedlings. The results are presented in Fig. 3 and indicate that the incorporated radioactivity is derived from $^{14}C_2H_4$. Treatment with base had no effect whereas treatment with all three ethylene trapping agents eliminated the observed effect. Furthermore, regeneration of the $^{14}C_2H_4$ from the specific ethylene complexing reagent, $Hg(ClO_4)_2$ (ref. 13) completely restored activity.

Ethylene metabolism in these seedlings is almost certainly biological since essentially no radioactivity was recovered in the tissue or as $^{14}CO_2$ when the seedlings were heated to 80 °C for 1 min before $^{14}C_2H_4$ exposure or when the $^{14}C_2H_4$ was applied in anaerobic conditions. Additional evidence supporting this view, as well as indicating the complexity of the ethylene

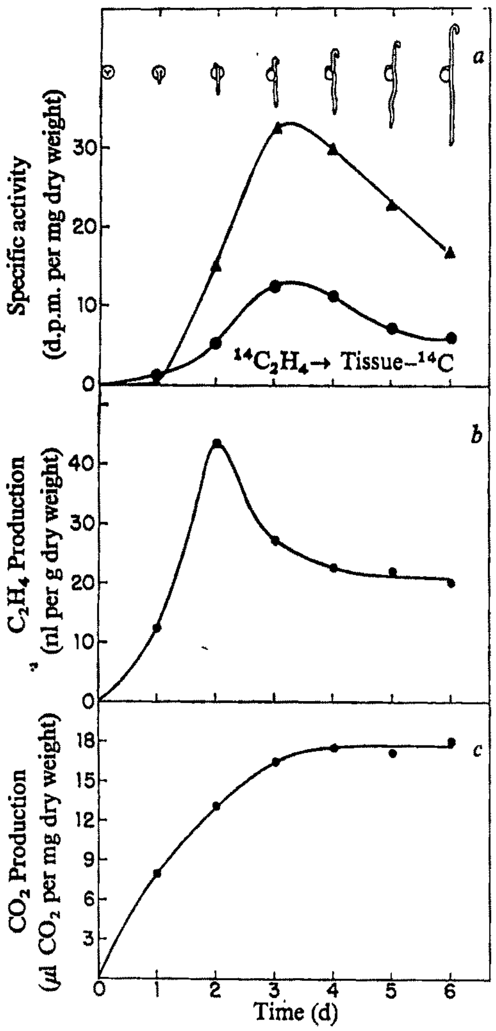

Fig. 2 *a*, Time course of $^{14}C_2H_4$ conversion to $^{14}CO_2$ (▲) and $^{14}C_2H_4$ incorporation into tissue components (●) of aseptically grown pea seedlings; *b*, natural ethylene production; *c*, natural CO_2 production. $^{14}C_2H_4$ specific activity was 22 mCi mmol^{-1}. Each datum point is the average of nine seedlings. Three such experiments were conducted with similar results. Pea seeds (*Pisum sativum* L. cv. Alaska) were rinsed with water and ethanol and surface-sterilised for 15 min in 1% sodium hypochlorite. The seeds were rinsed with 4 l of sterile water, treated for 10 min with 0.01 N HCl (ref. 14), rinsed again and placed in the dark in an equal volume of sterile water for 4 h at 27 °C. Following imbibition the seed coats were removed aseptically and the seeds rinsed four times with 4 l of sterile water. Sterilised seeds were germinated at 27 °C in the dark in Pyrex dishes between moist sheets of filter paper. Seedlings were transferred aseptically into 62 cm^3 flasks with glass centre wells and ground-glass stoppers. The freshly purified $^{14}C_2H_4$ was injected through a side-arm fitted with a 5 mm rubber serum stopper and the arm was immediately sealed off from the rest of the flask by rotating the stopper, as volatile substances from the serum stoppers often caused erratic results. Natural C_2H_4 and CO_2 production were determined in the same conditions as in (*a*) except that no $^{14}C_2H_4$ was added. CO_2 production rates were measured by liberating the CO_2 from the NaOH with acid followed by gas chromatography to determine the amount released. CO_2 production rates in conditions in which 10 µl l^{-1} ethylene was added were only slightly higher than in air. The radioactivity recovered in the NaOH was identified as $^{14}CO_2$ by liberating the CO_2 from the NaOH with acid and then isolating the CO_2 fraction by GC and comparing the radioactivity present in this fraction with the amount originally present in the NaOH. s.d. for $^{14}C_2H_4$ to $^{14}CO_2$ conversion (▲) in (*a*) for days 1 to 6 were ±0.7, 2.6, 5.8, 5.2, 1.4 and 0.4, respectively. The s.d. for $^{14}C_2H_4$ incorporation into the tissue (●) in (*a*) were ±0.2, 1.1, 2.4, 0.8, 0.3 and 0.2, respectively.

metabolism system, is the fact that ethylene metabolism was reduced over 80% if the cotyledons were detached from the seedlings during incubation of the whole seedling.

These experiments demonstrate that ethylene is incorporated and metabolised by intact pea seedlings. As yet, the possible physiological significance of this observation in terms of ethylene action is not clear. It is of considerable interest, however, that a peak of natural ethylene production should precede the peak in ethylene metabolism. This sequence does not seem to be the result of a delay in the peak of ethylene metabolism caused by a reduction in growth since the same sequence was observed in other experiments (E.B., unpublished) involving much shorter exposure periods in which the added ethylene had no detectable effect on growth. It is possible that ethylene action depends on its permanent incorporation into cellular components. Perhaps the peak in natural ethylene production and the peak in ethylene incorporation and metabolism reflects the progress of senescence in the cotyledons. The level of incorporation observed in these experiments could have been observed only through the use of $^{14}C_2H_4$ of high specific activity. I have found that CO_2, which often acts antagonistically to ethylene (ref. 1), will severely inhibit conversion of C_2H_4 to CO_2. This finding further suggests that ethylene metabolism and action may be closely linked.

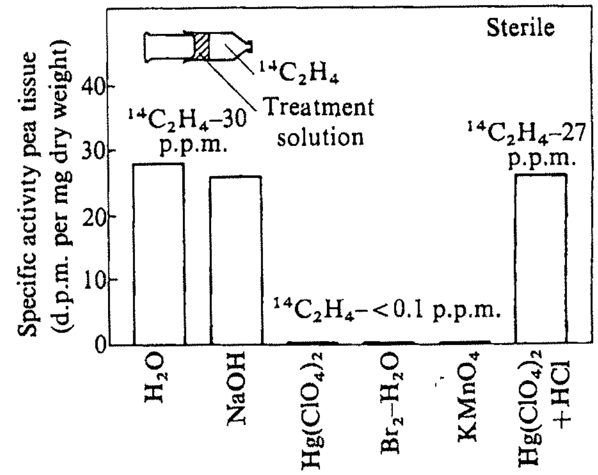

Fig. 3 The effect of pretreating purified $^{14}C_2H_4$ (specific activity 22 mCi mmol^{-1}) with water, NaOH, $Hg(ClO_4)_2$, Br_2–H_2O or $KMnO_4$ on its subsequent incorporation into aseptically cultured 2 d old pea seedlings. $^{14}C_2H_4$ (3 ml, 900 µl l^{-1}) was pretreated for 30 min over 1 ml of each treatment solution in a 5 ml glass syringe. The gas phase (2 ml) was then injected into a flask containing three pea seedlings and the seedlings were incubated for 24 h at 27 °C. Each datum point is the average incorporation of nine seedlings. The $Hg(ClO_4)_2$ solution was one-fifth the concentration recommended in ref. 13, thus eliminating the formation of impurities[8].

In view of the relatively large amounts of impurities found in all of the $^{14}C_2H_4$ samples purchased, it is difficult to assess the significance of previous studies. The instability of labelled ethylene is illustrated by the fact that within one week of purification, labelled radiolysis products could be detected. Previous studies[5,9,10] are further complicated by the fact that $^{14}C_2H_4$ was routinely regenerated from $Hg(ClO_4)_2$ before exposure to plant tissues. As reported by Jansen[8] and confirmed in similar experiments, this procedure leads to the formation of impurities which are readily incorporated into plant tissues. These criticisms raise considerable doubt as to the validity of previous studies and their significance must be evaluated on the basis of more critical experiments.

Alcohol selection by DBA and C57BL mice arising from ova transfers

THE notion of the hereditability of alcoholism has alternated between acceptance and rejection[1–4]. Convincing evidence for a genetic involvement in man has been reported[5,6], but the issue remains controversial[7]. Because nature and nurture are so intertwined, and the methodology of their separation in humans is difficult, and even often suspect, inbred mouse strains have been used to examine the genetic basis of the disparate voluntary alcohol intakes seen in these strains[8,9].

The transfer of fertilised ova between strains of mice exhibiting extremes of alcohol choice separates the contributions of heredity and environment. Measurement of the retention, or the loss, of strain-typical preference or aversion for alcohol in the offspring arising from fertilised ova transferred to a mother of a different strain then enables an estimate to be made of the relative contributions of heredity and environment to alcohol selection. Our findings uphold the hereditary basis of alcohol selection in C57BL mice, but show the avoidance of alcohol drinking by DBA mice to be amenable to environmental alteration.

Ova donors and recipients were primiparous adult female C57BL/6 (alcohol preferrers) and DBA/2 (alcohol avoiders) mice born in our colony from breeder stock purchased from Jackson Laboratories. The mice were housed in plastic cages (19 × 29 × 14 cm) covered with a wire-mesh top indented to hold Purina lab chow and cylinders of fluid graduated to 0.2 ml. A cycle of 12-h light and 12-h dark was used. Fifty-four offspring were used as subjects; their grouping and sexual composition are shown in Table 1.

Ova were transferred by a modification of the method of McLaren and Michie[10]. Donor females were used 3.5 d and recipient females 2.5 d after identification of a vaginal plug.

At birth, the litters were culled to a maximum of four pups, since no more than three transfers were born to one female; the remaining pups, ranging from one to three, were her own. Differences in eye pigment identified experimental pups at birth. In the case of control transfers (C57BL to C57BL and DBA to DBA), litters were culled to a maximum of four without respect to sex. The untreated controls were mated and housed in the same manner as the experimental and control transfer animals, but subjected neither to anaesthesia nor to surgery.

Pups were weaned at 25 d and housed individually for 7 d; during this time they were offered a choice between tap water and 7.5% ethanol (w/v, prepared from 95% ethanol). The fluids were presented in two 25-ml cylinders graduated to 0.2 ml and fitted with stoppers and ball-bearing spouts. Daily fluid consumption was measured and the tubes were alternated; the subjects were weighed every other day. A mean preference ratio (ml 7.5% w/v ethanol per ml of total fluid per d) and mean fluid intake (alcohol, water and total fluid per g body weight per d) were calculated for each subject based on the 7-d test period.

Table 1 Distribution of subjects among experimental groups

Group	Male	Female	Donor	Recipient	Condition
1	5	2	C57BL	DBA	Experimental
2	3	5	C57BL	C57BL	Control
3	6	4	—	—	C57BL untreated control
4	4	6	DBA	C57BL	Experimental
5	4	6	DBA	DBA	Control
6	7	2	—	—	DBA untreated control

Table 2 Mean body weight and mean fluid intake (±s.e.)

Strain	Group*	N	Body weight (g)	Water intake ($\mathrm{ml\ g^{-1}\ d^{-1}}$)	Alcohol intake ($\mathrm{ml\ g^{-1}\ d^{-1}}$)†	($\mathrm{g\ kg^{-1}\ d^{-1}}$)‡
C57BL	1	7	12.7±0.7	0.036±0.013	0.303±0.032	22.7±2.4
C57BL	2,3	18	12.0±0.3	0.090±0.015	0.174±0.013	13.1±1.0

*Refers to groups of Table 1.
†ml of 7.5% (w/v) ethanol per g per d
‡g of ethanol per kg per d.

Since no sex differences were noted in either strain, the sexes were pooled and treated as one; the two control groups for each strain (untreated mice and transfers to the same strain) were not statistically different from each other and these data were also combined for analysis. The group means (± s.e.) for the various measures are shown in Table 2.

An analysis of variance for a complete orthogonal set of contrasts for the transfer and strain variables was carried out. Strain differences were highly significant for body weight, water and alcohol intake, preference ratio, and g ethanol per kg per day ($F = 5.73–65.2$, d.f. $= 1/50$, $P = < 0.000001–0.021$). C57BL mice weighed more, drank more alcohol and less water than the DBA mice. Collapsing across strains, treatment condition (transfer compared with non-transfer) was significant for water and alcohol consumption, preference ratio and g ethanol per kg per day ($F = 7.04–22.59$, d.f. $= 1/50$, $P = 0.000017–0.011$). Control mice of both strains drank less alcohol and more water than transferred mice. The strain × treatment interaction was significant only for the water, alcohol and g of ethanol per kg per day measures ($F = 4.29–10.26$, d.f. $= 1/50$, $P = 0.0024–0.044$). Mice arising from transferred ova of both strains thus drank less water and more alcohol than their respective control groups. No differences in total fluid intake were noted.

Our results support previous findings[8,9] that alcohol preference in the C57BL strain has a genetic basis, but provide even more conclusive evidence. Offspring arising from drinker ova transferred to the uterus of a non-drinker mother and raised by her not only retained, but increased their strain-typical high alcohol preference. We cannot offer a convincing (factually based) rationale for this increase. The offspring arising from fertilised non-drinker DBA ova transferred to drinker C57BL mothers also increased their alcohol intake and thus failed to retain their strain-typical aversion to alcohol, suggesting that either the prenatal or postnatal environment, or a combination of the two, is sufficient to increase alcohol consumption in DBA mice. Support for a positive postnatal rearing effect has been reported by Komura *et al.*[11] in normal (non-transferred) mice and we have confirmed[12] this; DBA offspring fostered by C57BL mothers from birth to weaning increased their voluntary alcohol consumption, but in C57BL weanlings (pups fostered by DBA mothers) alcohol intake was unaffected. These results do not, of course, preclude the possibility that the prenatal environment is of equal importance: a cross-fostering study of offspring from transferred ova would be required to partition accurately the maternal effects.

Our results support the genetic basis of alcohol selection in the C57BL mouse, the nature of which is still unknown, while demonstrating that alcohol avoidance in DBA mice is subject to environmental manipulation. The identification of those physiological and/or biochemical factors under genetic control and determining alcohol preference should appear high on any list for investigation.

Although research on the genetic aspects of alcohol preference in mice may serve to further the understanding of the predisposing role of inherited factors, any results garnered from such research cannot easily be generalised for their applicability to the problems of alcoholism in man.

We thank Dr Benson Ginsburg and Ms Alice Trottner (University of Connecticut) for help with the surgical procedure. This research was supported by grants from the Busch Memorial Fund (predoctoral fellowship to C.L.R.) and a biomedical sciences support grant from Rutgers University, the US National Institute on Alcohol Abuse and Alcoholism and the Distilled Spirits Council of the United States. Dominance at *Adh* locus in response of adult *Drosophila melanogaster* to environmental alcohol

IT has been argued[1] that natural selection acting on enzyme polymorphisms may be most clearly demonstrated by challenging polymorphic populations with an environmental additive acting as a specific substrate for the enzyme under study. Wills and Nichols[2], for example, showed that, in their experimental conditions, heterozygote advantage at the octanol dehydrogenase locus in *D. pseudoobscura* depended on the presence of octanol in the food medium. Similarly, de Jong *et al.*[3] found that the amylase^{4,6} variant increased strikingly in frequency in populations of *D. melanogaster* moved from a sucrose to a starch-rich food medium. $Amy^{4,6}$ is known to possess the highest *in vitro* activity on starch substrates of all common amylase variants[4]. We have examined the relationship between mortality and genotype at the alcohol dehydrogenase (*Adh*) locus when adult *Drosophila* are exposed to environmental ethanol.

Table 1 *Adh* genotypes among wild-caught *D. melanogaster* from a wine cellar and neighbouring rubbish tip

	Adh genotype			Frequency of Adh^F
·	Adh^F/Adh^F	Adh^F/Adh^S	Adh^S/Adh^S	± s.e.
Wine cellar	177	15	0	0.961±0.010
Rubbish tip	152	37	3	0.888±0.016*

*The two samples differ significantly $P<0.001$.

Wine cellars in Spain support extremely large populations of *D. melanogaster* that feed on, and breed in, the fermenting and maturing liquor (12–15% ethanol) impregnating floating mats at the surface of wine jars. Neighbouring rubbish tips and grape-skin composts also sustain populations. It seems probable that all the *D. melanogaster* within a town, and perhaps within a much larger region, form a single breeding unit, as we have observed considerable migration between bodegas (wine cellars). Recent studies of lethal allelism have indicated that samples of *D. melanogaster* collected at sites as much as 1.4 miles apart may belong to the same population[5]. We would therefore attribute any local differentiation of allele frequencies to selective values differing between sites, rather than to the sites representing independent discrete populations.

As might be expected, the Adh^F allele, whose enzyme product has a higher ethanol catalytic activity per individual than that of the Adh^S alternative, is at a high frequency (0.94–1.00) in cellar populations throughout Spain (D.A.B., J-M.M., and A.R., unpublished). The Adh^S allele is more favoured in non-cellar environments, being at a significantly higher frequency in a rubbish-tip sample than in our standard (Mancha) wine cellar, although the two sites are less than 1 km apart (Table 1). Similarly, the frequency of Adh^S increases dramatically in laboratory populations bred from large ($\sim 10^4$ adults) samples removed from wine cellars (D.A.B., J-M.M., and A.R., unpublished).

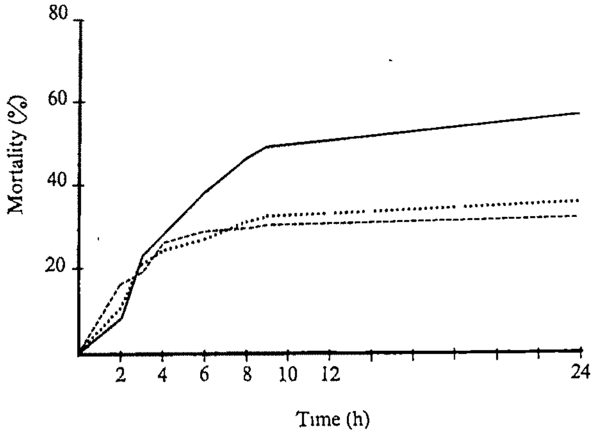

Fig. 1 Mortality/time plots for the three *Adh* genotypes when adult *D. melanogaster* are allowed to feed on medium containing ethanol (12.5%). ———, Adh^S/Adh^S; ...., Adh^F/Adh^S; ----, Adh^F/Adh^F.

We have tested the proposition that alcohol is the major environmental factor maintaining a high frequency of Adh^F in wine cellars by exposing adult flies to ethanol in a situation which mimics that confronting *Drosophila* entering a cellar and feeding on wine. Flies from the Mancha and Mandila population cages (which had been initiated 18 and 6 months previously with samples from two cellars 200 km apart), and from the standard Kaduna laboratory population, were placed in beakers. A Petri dish containing food (Edinburgh medium[6] supplemented with ethanol to a concentration of 12.5%) was fixed to the mouth of each beaker. The food was replaced every 2–3 h to maintain the concentration of ethanol. The *Drosophila* readily fed on this medium. Flies which died were removed and immediately electrophoresed to determine their *Adh* genotype. All individuals which survived were removed at 24 h and electrophoresed. No death occurred in controls in which the medium was supplemented with distilled water.

A typical mortality–time profile is shown in Fig. 1. Mortality is expressed as a percentage [(number of individuals of a given genotype dead after a given time/total number of that

Table 2 Mortality (%) of the three *Adh* genotypes after 24 h exposure to ethanol food

Population	*Adh* genotype Adh^F/Adh^F	Adh^F/Adh^S	Adh^S/Adh^S	Increase in frequency of Adh^F allele
Mandila (starved)	33.2 (211)	34.5 (258)	54.8 (62)	+0.0269
Mancha (starved)	43.2 (229)	45.6 (237)	74.5 (51)	+0.0430
Mancha (prefed)	12.4 (145)	16.5 (133)	36.4 (22)	+0.0192
Kaduna (starved)	68.2 (110)	69.9 (103)	91.7 (24)	+0.0612
Kaduna (prefed)	25.3 (99)	32.1 (109)	45.8 (24)	+0.0278

Total numbers of each genotype in the sample are given in parentheses.

genotype in the sample) × 100]. It is clear that mortality occurred predominantly during the first few hours of exposure. Accordingly the results for all samples have been expressed as total mortality (%) for each genotype after 24 h on ethanol food (Table 2). These data demonstrate a clear differential mortality between the genotypes, the Adh^S/Adh^S homozygote being significantly less resistant to alcohol poisoning than the heterozygote or Adh^F/Adh^F homozygote. The resulting increases in the frequency of Adh^F (frequency in survivors minus frequency in the sample before treatment) are given in Table 2. Increasing the rate of feeding, and hence of alcohol uptake, by starving the flies for 24 h in a humid chamber before treatment, significantly elevated the overall mortality.

In view of the strong selection against Adh^S in the presence of ethanol it is surprising that this allele is present at all in wine cellars. Presumably some form of balancing selection acting at other stages of the life cycle, or gene exchange with non-cellar populations, maintains the low frequency. Note that *Adh* alleles are not in linkage equilibrium with respect to other loci in Spanish populations, Adh^S being held in an inversion together with α-$Gpdh^F$ (D.A.B, J-M.M., and A.R., unpublished). Selection for or against Adh^S therefore acts on the entire contents of the inversion, and conversely, selection at other loci within the inversion will influence the frequency of Adh^S. Nonetheless, we consider that the observed mortality differences between genotypes are due primarily to the *Adh* locus, and not to selection acting on a linked locus, as the results from the Spanish populations are strictly comparable with those from the Kaduna population, which lacks inversions and detectable linkage disequilibrium.

McKenzie and Parsons[7] report that Chew failed to detect significant gene frequency differences at the *Adh* locus between Australian wine cellars and neighbouring non-cellar sites, and discount the alcohol dehydrogenase (ADH) system as a component of alcohol tolerance in *D. melanogaster*. Our results lead us to an opposite conclusion. If the treatment described above is a reasonable reflection of a natural situation we must conclude that the Adh phenotype expressed in an individual fly is an important component of its ability to tolerate environmental alcohol and, likewise, that adult mortality in the presence of ethanol-rich food plays a major role in maintaining a predominance of the high-activity Adh^F allele in wine-cellar populations.

Table 2 also shows that, in terms of survival on ethanol, the Adh^F allele is effectively dominant over the Adh^S alternative. This is at first sight surprising as all published data, and our own unpublished work, are in agreement that the *in vitro* ADH activity of *Adh* heterozygotes does not deviate consistently from the mid-point between the two homozygotes[8–11]. For example, the ratios of the mean specific activities of the Adh^F homozygote, heterozygote and Adh^S homozygote in the Mancha and Kaduna populations are 3.25:2.24:1.00 and 1.91:1.41:1.00, respectively (D.A.B, J-M.M., and A.R., unpublished). Additivity at the primary gene-product level but dominance at the physiological level are, however, the general observations, where data on inborn errors of metabolism are available[12,13]. Further, this relationship has been shown to be a general expectation derived from theoretical analyses of enzyme systems (ref. 14 and J. A. Burns, and H. Kacser, unpublished) and the data presented here support that prediction.

Dominance may influence the maintenance of a polymorphism in two ways. First, directional selection in a single environment becomes increasingly ineffective as the recessive allele becomes rare, thus dominance protects the recessive allele from extinction when a population encounters an environment in which the recessive is at a disadvantage. Secondly, should the dominance relationships be reversible under alternative conditions within a temporally or spatially varying environment, a marginal heterozygote advantage may result which could actively maintain the polymorphism.

Maintenance of allozyme polymorphisms in experimental populations of *Drosophila*

A CONTROVERSIAL point in modern population genetics is whether allozyme variation is adaptive or neutral. The interpretation of gene frequency distribution in terms of components of the environment[1–4] for a given species, or in terms of the comparison of patterns of allelic variation among different species[5,6], are cited as evidence of selection. Support for the alternative hypothesis derives from the apparent agreement between models based on neutrality and empirical findings either for the distribution of amino acid substitutions in proteins[7,8] or for the distribution of heterozygosity[9]. These arguments have been challenged on theoretical grounds[10,11], as well as on the basis of the distributions of allelic frequencies found in natural populations[12,13].

The selective value of allozyme polymorphisms may be assessed by testing allozyme systems under experimental conditions. We have used this method to study several experimental populations and look for changes in allozyme frequencies through the generations. Results reported here indicate that selection is probably responsible for the changes in gene frequencies observed in our experimental populations. These changes are, however, also influenced by the adaptive value of the genetic background that interacts with the allozyme genotypes under study.

The loci under study were *Est-5* (*X chromosome*), *Mdh-2* (IV) and *Odh* (II) in *Drosophila pseudoobscura*. For the *Est*-5 locus, 19 independent homozygous strains were obtained by brother×sister matings from the progenies of wild females collected recently at McDonald Ranch (Coast Ranges of Northern California). For the *Mdh-2* and *Odh* loci we similarly obtained 31 and 19 independent strains, respectively. This represents a large number of independent chromosomes sufficient to avoid any kind of large artificial linkage disequilibrium at the beginning of the experiment.

For each of these three enzyme loci two population cages (A and B) were started each with about 3,000 individuals. The founder individuals were obtained from the strains mentioned above, combined in appropriate numbers to start one cage (A) with a high initial frequency (0.80) of the rare naturally occuring allele (respectively, *104, 112* and *104* for *Est-5, Mdh-2,* and *Odh*), and another cage (B) with a low initial frequency (0.20) of that allele. The experimental populations were maintained and sampled at regular intervals for more than 600 d. Figure 1*a–c* shows the results. Gene frequencies have changed significantly in every one of the A cages, but the B cages do not show evidence of significant changes. The two *Est*-5 cages may have attained a common equilibrium level, but this result must await future generations of sampling for confirmation. Most significant is that all the changes in the A cages are in the same direction, namely towards the natural gene frequencies.

In every one of the A cages there was a large initial drop in the frequency of the rare allele. As a result of the rarity of this allele in nature, the original homozygous strains for this rare allele were more inbred than the homozygous strains for the commonest allele, and this may be the cause of the low initial fitness values of the genotypes with the rare allele. To test this possibility we crossed the original homozygous strains for the *Est*-5^{104} in pairs, using each strain in two crosses, as the male parental in one cross and as the female parental in a different cross. The F_1 progenies of these crosses were again crossed in pairs and this procedure was continued for five generations, to obtain a unique strain still homozygous for *Est*-5^{104} but with a largely heterozygous genetic background. This same procedure of matings was used with the strains homozygous for *Est*-5^{100}. With these two outcrossed strains we started two new population cages with high (cage 80) and low (cage 20) allele frequencies, similar to the A and B cages described above. Figure 1*d* shows the changes in gene frequencies observed during the first 500 d of sampling. The initial drop for allele *Est*-5^{104} of cage 80 is similar to that of cage A (Fig 1*a*); this rules out the effect of inbreeding as a major factor responsible for the initial drop of the rare allele in the original cages.

An interesting feature of the results (Fig. 1*d*) is that the *Est*-5^{104} allele now seem to be levelling off at a higher frequency than it did previously in cage A. *Est*-5 strains had been kept in the laboratory for one year (about 12 generations) before the serial crosses were started to obtain the outcrossed lines. Under the prolonged overcrowded environment of the cultures one might expect selection to favour genes which increase genotype efficiency to compete and to exploit this kind of environment (K-selection). Adaptive changes caused by modifier genes have been reported not only in allozymes[15,16] but also in morphological mutants[17–20] caused by directed selection or in response to laboratory conditions. We propose that selection for these modifier genes associated with the *Est*-5 locus may have occurred during this time, and that this may be a major reason for the increase in fitness shown by the genotypes with *Est*-5^{104} allele.

Yamazaki[22] did not find significant selective differences between two alleles of *Est*-5 locus in *D. pseudoobscura*. The flies used in his experiment, however, were extracted from an experimental population cage which had been previously kept in laboratory conditions for many years. These

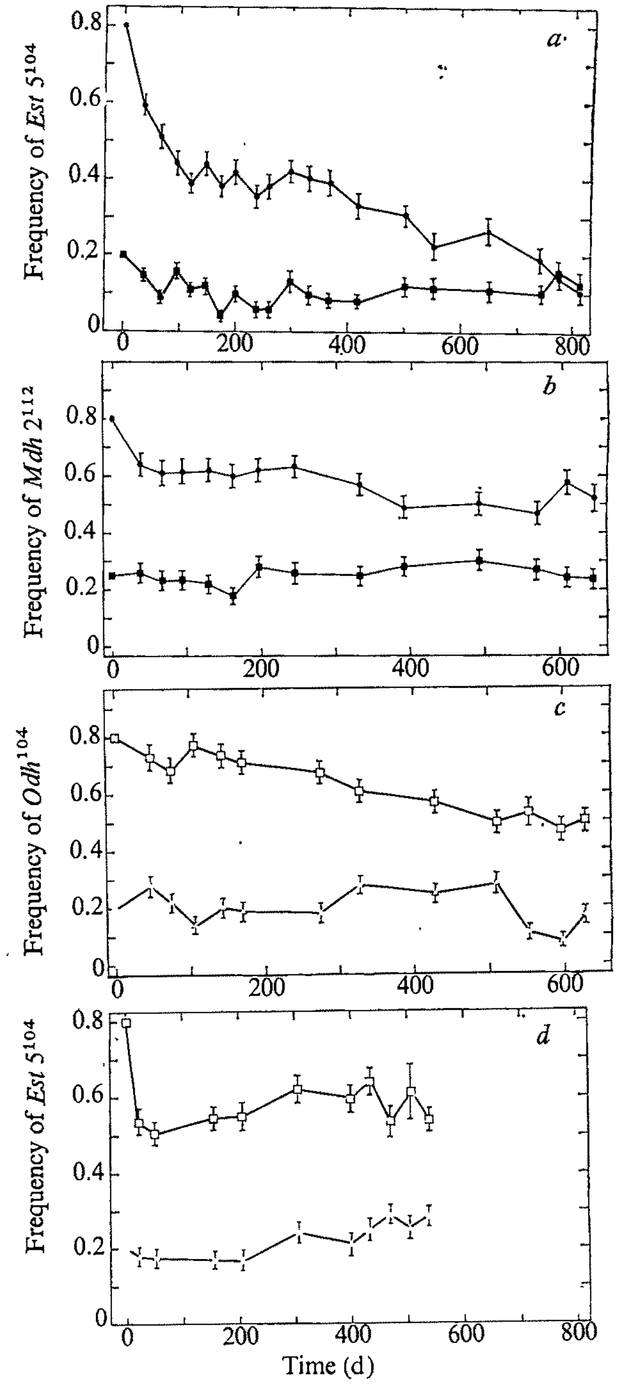

Fig. 1 *a*, Mean frequencies (95% confidence intervals) of allele *Est*-5^{104} of *D. pseudoobscura* in two experimental population cages, A (●) and B (■). The other allele present in the cages is *Est*-5^{100}. Each point is based on two samples of about 150 eggs taken from each cage during 3 consecutive days. Each individual sample of eggs was placed in a separate culture from which we sampled at random 24 emerged females. The genotypes of these females (a total of 144 per cage per sample) were analysed for the *Est*-5 locus using starch gel electrophoresis[24]. *b*, Allele *Mdh*-2^{112} in cage A (●) and B (▲). The other allele present in the cages is *Mdh*-2^{100}. Sampling as in (*a*) except that the total number of flies subjected to electrophoresis was about 96 per sample. *c*, Allele *Odh*^{104} in cage A (□) and B (△). The other allele present in the cages is *Odh*^{100}. Sampling as in (*b*). *d*, Allele *Est*-5^{104} in two experimental cages, 80 (□) and 20 (△). Sampling as in (*a*).

populations may well have built up a high adaptation to the experimental conditions through the selection of highly adapted favourable gene modifiers. The presence of these modifiers may obscure the detection of small differences in fitness between *Est*-5 alleles.

The fact that selection is not operating exclusively and directly on allozymes but also simultaneously on other interacting genes does not rule out selection as responsible for the maintenance of allozyme polymorphisms. The uniformity of response in all the initial cages (A, B) in the present experiment towards frequencies close to the naturally occurring ones, is not what would be expected if the allozymes were neutral and associated randomly with other genes subjected to selection. If this were the case, one should find a variety of responses[21].

Marinkovic and Ayala[23] have tested several fitness components for the same genotypes we used and their results are consistent with the view that selection is operating on the three loci we studied. Our results also indicate that selection must be acting on these loci, if not directly, at least through a series of coadapted gene complexes in which the allozymes genes are integrated.

Do blue-eyed people have more sensitive corneas than brown-eyed people?

IT has sometimes been noted by opticians involved in the fitting of contact lenses that the sensitivity of the cornea seems to vary, depending on whether the patient has blue or brown eyes. Since it is likely that the sensitivity of the cornea reflects general tactile sensitivity, this knowledge could be valuable. Because there does not seem to be any quantitative report of this phenomenon, I carried out an experiment in which corneal sensitivity to touch could be compared among people with different eye colour.

The Cochet-Bonnet aesthesiometer[1] was used to stimulate the cornea. Two models of the instrument, with nylon monofilament of 0.12 and 0.08 mm diameter, were used to produce pressures from 11–200 mg/0.0113 mm^2 and from 2–90 mg/0.005 mm^2, respectively. Both aesthesiometers are interchangeable and had previously been calibrated. The aesthesiometer was mounted in a holder such that it could be moved in *x*, *y* and *z* axes by means of three knobs. Thus, it was possible to achieve reliability in stimulation of a corneal point, a steady speed of application and a perpendicular corneal contact. A corneal point near the limbus in the six o'clock position was stimulated and the slightest bend of the nylon wire visible through a magnifier was defined as corneal contact. The inferior corneal point was chosen because the touch threshold measured there is not affected by psychological factors[2].

Measurements of corneal touch thresholds were made subjectively[3]. The experiment began with stimulation of the cornea with the lowest pressure and continued in an ascending fashion. At each predetermined length of the nylon monofilament (with increments equal to 0.5 cm with each instrument), four to six contacts were made with at least one blank to test the subject's reliability. The subject indicated when he felt the probe by pressing a bell. From these measurements the corneal touch threshold was defined as the length of the monofilament at which the subject responded for 50% of the number of stimulations. This length was converted into pressure using a previously calibrated curve for the instrument. The tolerances for this test are within ±5% as evinced by repeated measurements on the same subjects.

Caucasian subjects (112) 21–37 yr old (mean 23.5) participated in this experiment. Another group of 44 non-white subjects 22–33 yr old (mean 24.2) comprising 12 Negroes, 15 Indians and 17 Chinese, also served as subjects. As all these people (except four) were university students, they were about the same age in each group. All subjects were free of ocular pathology. The

Fig. 1 Relative corneal sensitivity to touch as a function of the colour of the eye. The dark brown group consists of the non-white subjects. The sensitivity is the reciprocal of the touch threshold measured in mg mm^{-2} and the group with the greatest sensitivity has been assigned 100% in this diagram.

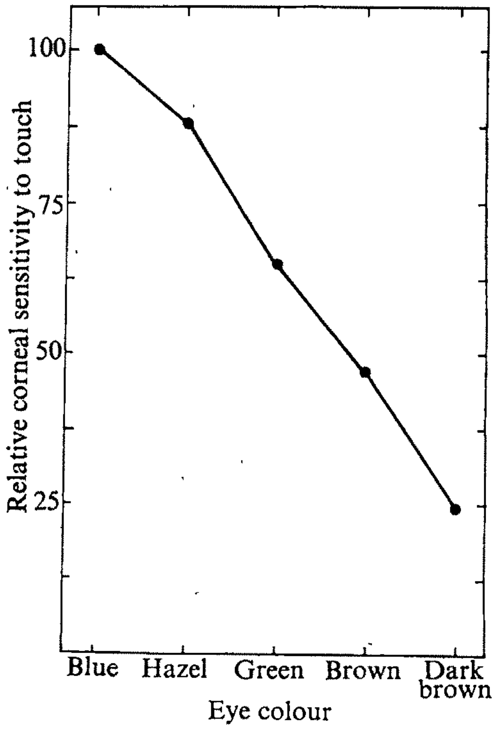

Table 1 Corneal touch threshold ($mg\ mm^{-2}$) in people with different iris colour

	Blue	Hazel	Green	Brown	Dark brown			Total
					Indians	Negroes	Chinese	dark brown
No. of subjects	39	12	12	49	15	12	17	44
Mean	14.3	16.2	22	30.4	47	61.6	64.5	57.8
S.d.	4.7	7.4	13.3	19.0	14.8	22.5	21.2	20.8

subjects were separated into groups according to the colour of the iris: blue, hazel, green, brown and the darker brown eyes of the group of non-whites.

The corneal touch thresholds obtained in variable order with these people are given in Table 1. These values were converted into sensitivity (threshold^{-1}) and the greatest sensitivity value was assigned 100%. The relative corneal sensitivity to touch for the various groups is illustrated in Fig. 1, in which there is only one group of people with dark brown eyes representing the non-white subjects.

The results of this study provide strong evidence that people with blue irises have the most sensitive corneas and people with brown eyes least sensitive; the sensitivity further diminishes in non-whites with darker pigmented eyes. It can also be seen (Fig. 1) that blue-eyed people have, on average, twice as sensitive corneas as white people with brown eyes (difference statistically significant, $P < 0.001$). The mean corneal touch threshold (and standard deviation) of all Caucasian females ($n = 55$) was 23.91 $mg\ mm^{-2}$ (s.d. 16.01) and of all Caucasian males ($n = 57$) 21.06 $mg\ mm^{-2}$ (s.d. 14.9). The difference between sex is not significant ($P > 0.5$), although it is worth noting that females are slightly less sensitive than males by about 10%. This factor may be accounted for by the fact that women have much less sensitive corneas for about 3 days at about the time of menstruation compared with the rest of the month[4].

It also seems from the present study that non-white people who have dark brown irises have much less sensitive corneas than white people. The difference between the group of white people with brown eyes and the non-white is significant ($P < 0.001$). The present results show that non-white people have, on average, four times less sensitive corneas than blue-eyed people and half as sensitive corneas as whites with brown eyes.

It could be argued that the variations displayed here were caused by the fact that corneal sensitivity varies diurnally[5] but this is unlikely as the diurnal variation is considerably smaller than the differences between eye colour.

This phenomenon is obviously relevant to the wearing of contact lenses. It may also have some bearing on problems of anaesthesia as it is possible that different quantities of anaesthetics may be needed according to eye colour. It may be inferred that corneal sensitivity reflects the general sensitivity of the body; and there is some evidence supporting this view as it was found that at about the time of menstruation corneal sensitivity is reduced[4], and the touch sensitivity of the middle finger is diminished[6].

This hitherto unreported phenomenon may help to explain large variations in corneal sensitivity in normal subjects. This variation can be puzzling when comparing the effect of some treatment or disease on the eye against a group of control subjects; this has already been noted in a study[7] of corneal sensitivity in diabetics.

It is already a known clinical fact that, in the eye, more drugs are needed on people with dark rather than with light-pigmented irises to obtain the same effect (for example cycloplegia). The reason for this is not known although it may be related to the amount of melanin pigment present in the iris, where ocular drugs have an effect. Since the cornea does not contain any such pigment, however, it is not easy to explain the diminution of corneal sensitivity with darker pigmentation of the iris. It is not known whether the thickness of the cornea varies with eye colour. It has been shown[8] that thicker corneas, as a result of oedema, are less sensitive than normal corneas. It is also unknown whether nerve density varies widely among these different people. An alternative possibility is that the difference in sensitivity may arise in the central nervous system and not at the periphery. The difference in tactile sensitivity may also be relevant to understanding that the practice of acupuncture may be more acceptable in China than it is in countries inhabited by blue-eyed people.

Iris colour and relationship of tyrosinase activity to adrenergic innervation

IRIS colour to some degree depends on the sympathetic innervation of the eye. Chance clinical observations of humans and experimental studies in animals have demonstrated consistently a gradual lessening of colour intensity in the iris after interruption of the sympathetic pathways to the eye[1,2]. Similarly, full iris pigmentation fails to develop when the sympathetic innervation to the eye is absent from birth[3]. Interest in the relationship of sympathetic innervation to iris colour has increased with reports of direct adrenergic innervation to iris stromal melanocytes[4–6]. For mammals this is extraordinary in that most melanocytes, for example those of the skin, have no innervation. We have investigated this relationship using tyrosinase activity as an index of melanin synthesis since melanin is the chief pigment of the iris and tyrosinase is the rate-limiting enzyme in the production of melanin[7]. In turn, iris tyrosinase activity was measured in normal rabbits and in rabbits in which the sympathetic pathways to the eye have been interrupted.

Twenty-eight brown-eyed, Dutch belted rabbits of either sex with an average weight of 2.3 kg were used. In 10 animals the superior cervical ganglion on one side was resected under direct visualisation whereas in 18 animals the preganglionic nerve trunk was interrupted. To distinguish between the two types of operation the terms denervation and decentralisation are commonly used[8]. The occurrence of ptosis and miosis postoperatively was accepted as evidence that surgery had been successful. Survival times varied from 1 to 370 d. In all animals that survived longer than 2 months, the iris on the operated side became noticeably lighter in colour than that in the other eye.

Tyrosinase assays were performed in duplicate according to a modification of the method of Pomerantz[9]. Iris tissue, either homogenised or intact, was placed in a solution containing sodium phosphate buffer, 0.01 M, *p*H 6.8, and L-tyrosine-3,5-^{3}H, 10^{-5} M, specific activity 50 $Ci\ mol^{-1}$. The mixture was incubated at 37 °C for 2–5 h. At the end of the reaction period, the material was treated with Norit SG to remove all tritiated substrate as well as tritiated reaction

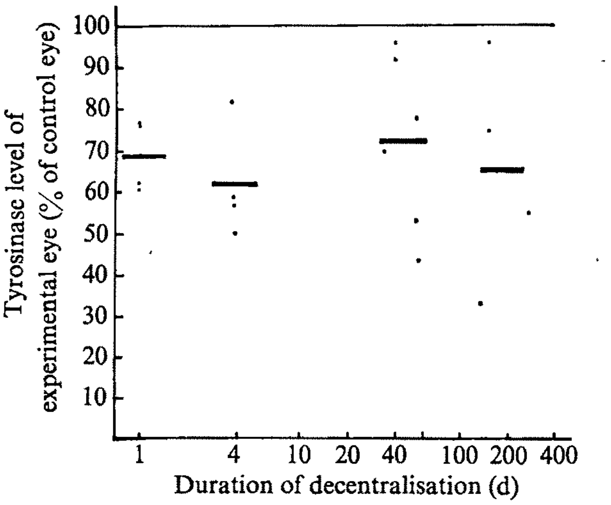

Fig. 1 After decentralisation of the superior cervical ganglion, iris tyrosinase activity declines rapidly. Once diminished, tyrosinase activity continues at the new, lower level for many months.

products except for tritiated water. An aliquot of the tritiated water was counted in a liquid scintillation counter. The activity of samples from iris tissue was calculated on the basis of c.p.m. per mg wet weight of tissue. Blanks for the assays consisted of either the reaction mixture without iris tissue or the reaction mixture plus iris tissue from an albino eye.

After either decentralisation or denervation, enzyme activity decreased in the ipsilateral eye. The results for both sets of animals are summarised in Table 1. The magnitude of the decline in iris tyrosinase was the same irrespective of surgical procedure. It should be remembered that the iris not only contains innervated iris stromal melanocytes but also has a posterior double lining of densely pigmented epithelial cells. Thus the proportion of the decline of iris tyrosinase activity that is attributable only to the iris stromal melanocytes cannot be told from these studies

When the assay results were plotted to show tyrosinase activity as a function of duration of decentralisation (denervation is similar but not illustrated here) (Fig. 1) we found that enzyme activity in the iris decreased within 1 d and remained depressed for at least 200 d Further, the assays of tyrosinase activity in the choroid (the posterior part of the uvea) in the same eyes yielded a similar rapid and long lasting decrease in enzyme activity.

In the face of such a clear-cut result, it seems reasonable to suggest a failure of maintenance, that is, to ascribe the lightening of iris colour that follows interruption of the sympathetic pathways to the eye to the inadequate replenishment of melanin within iris stromal melanocytes Thus as the melanin of the iris is slowly depleted by normal metabolic processes, the iris gradually loses colour. Although there is no electron microscopic evidence at present for metabolism of iris melanin[10], there has been a gradual build-up of information concerning degradation of melanin-containing bodies (melanosomes) in epidermis[11] and in certain preparations *in vitro*[12].

In its dependency on adrenergic innervation, ocular tyrosinase is not unique; it has become clear that an intact innervational network is a prerequisite for the regulation of enzyme levels in several organs innervated by the sympathetic nervous system. Perhaps the most interesting example of this type of regulation occurs in the pineal gland where under the influence of noradrenaline, levels of *n*-acetyltransferase can increase thirtyfold in a few hours[13–14].

Adult thymectomy results in loss of T-dependent mitogen response in mouse spleen cells

THERE is overwhelming evidence that murine thymocytes represent a heterogeneous population of cells that can be divided into discrete subpopulations on the basis of surface antigen markers[1,2], drug sensitivity[3], physical characteristics[4,5] and responsiveness to mitogens[6]. There is some indication that a similar heterogeneity with regard to biological function exists within the peripheral thymus-derived (T) lymphocyte population (reviewed in refs 7–9). Several investigators have shown that thymectomy of young adult mice reveals a differential sensitivity of several T-cell activities to this surgical procedure and suggested the existence of T-cell subsets with different life spans[7–9]. Therefore we investigated the response to PHA and concanavalin A in adult thymectomised (ATX) mice to determine if responsiveness to these mitogens could be attributed similarly to subpopulations of T cells.

We report here that spleen cells from BDF$_1$ mice thymectomised when 4 weeks old exhibit an initial increase in T-dependent mitogen responsiveness over age and sex matched littermate sham-operated controls (STX) followed by a rapid and sustained decay of responsiveness to these same mitogens, and that the response of identical cell preparations to a thymus-independent B-cell mitogen, lipopolysaccharide (LPS), does not show this divergence of responsiveness when thymectomised animals are compared with controls.

Of five experiments carried out, all gave similar results, and Fig. 1 shows the results of a representative experiment.

Adult thymectomy initially caused an increase in the response of spleen cells to phytohaemagglutinin (PHA) and con A. This was soon followed by a precipitous decrease in the level of con A and PHA responsiveness of cells from ATX animals while those from STX mice continue to increase to their mature adult level of responsiveness.

The response to pokeweed mitogen (PWM) (not shown here) was also lower in ATX animals although the differences were not as striking. In contrast, the response to LPS, though erratic, was similar in both normal and ATX mice. The 50% depression in these animals 20–38 weeks after thymectomy was not a consistent finding; in some experiments ATX cells gave a higher response than STX cells in these older mice. Most investigators agree that this mitogenic response occurs in the absence of T cells. If any T-cell component is involved, it is too small to have been detected in these experiments.

We have explored the response of these animals further and examined the kinetics, mitogen dose–response, variation in the number of cells cultured, and the substitution of foetal bovine sera for adult human sera. In all cases the responses of ATX animals to PHA and con A were depressed between 8 and 26 weeks after thymectomy compared with STX controls.

The decay in mitogen responsiveness seen here is consistent with the existence of two populations of T cells—one required for the bulk of the response to mitogens which decays completely by 9 weeks after thymectomy, and another long lived, responding poorly to PHA and con A. Although there have been several reports that adult thymectomy has no effect[10], or a transient effect[11–13] on mitogen responsive cells, some investigators have observed a decline in certain T cells subsequent to the same procedure. Raff and Cantor[7] and Kappler *et al.*[8] have demonstrated a diminution of precursors of T helper cells within 6 weeks after adult thymectomy. Futhermore, the number of Thy 1.2 positive cells in the spleen decreases by 5 weeks after adult thymectomy, caused primarily by a loss of those cells with a high rather than a low density of that antigen[9]. Moreover, rapidly dividing T cells found primarily in the spleen of normal mice are more sensitive to the cytolytic activity of anti-Thy 1.2 (ref. 14) and are required for the mitogenic response to PHA[15]. These results have been attributed to the presence of a short lived splenic T cell responsible for PHA responsiveness and possessing a high density of Thy 1.2.

The time course of the response in ATX mice (Fig. 1) is not clearly separable into decay curves of two cell populations. It therefore could be argued that it represents the decay of one long lived cell activity. In this case mitogen responsiveness should not drop off so rapidly unless maintenance of existing T-cell activity is thymus-dependent. Removal of the thymus does, of course, prevent further maturation of cells in the thymus and periphery. To the extent that maturation results from peripheralisation of cells from the thymus, thymectomy would abolish emigration. A deficiency in continued maturation would suffice to explain the inability of ATX mice to achieve the high levels of PHA and con A responsiveness seen in controls between 10 and 20 weeks of age.

The lesion in mice thymectomised as young adults is seen here as an inability to reach mature levels of responsiveness to PHA and con A and a decline of existing reactivity to these mitogens by loss of either a responding cell or an

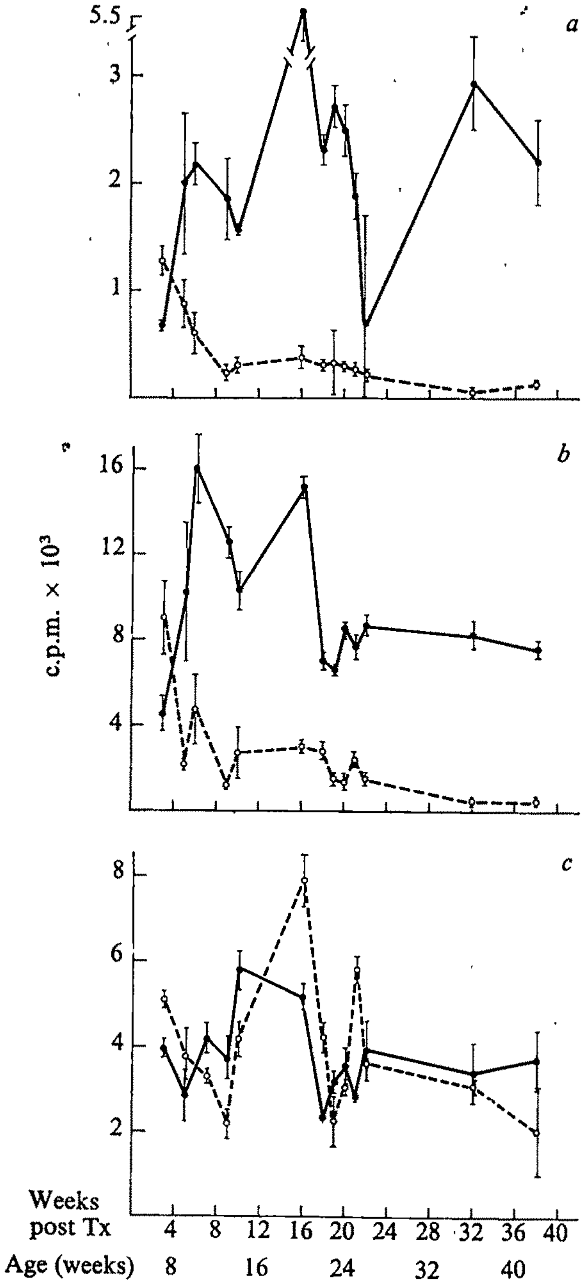

Fig. 1 Responses of 2.5×10⁵ spleen cells from ATX (○) and STX (●) BDF₁ mice to (*a*) PHA, (*b*) con A, and (*c*) LPS at indicated times after thymectomy. All 26 pools of spleen cells were cultured simultaneously with the various mitogens. Female BDF₁ (C57BL/6 female×DBA/2 male) mice bred at the University of California, San Diego, or purchased from Jackson Laboratories were used in all experiments. They were subjected to complete thymectomy (TX) or sham-thymectomy at 4 weeks of age, under light Avertin anaesthesia according to the technique of Dischelar and Rudali[16]. On the day of the experiment animals were killed by cervical separation, the spleens removed aseptically and single cell suspensions prepared as described previously[17]. Counts and viability determination were obtained using a haemocytometer and trypan blue dye exclusion. The cells were then resuspended in RMPI-1640 (GIBCO) which was supplemented with 10% adult human serum from one of us (W.B.). 2.5×10^5 cells in 100 µl were then added to individual wells in microtitre plates (Cooke Engineering Co., Alexandria, Virginia) and a further 100 µl added of either mitogen in serum-free medium or serum-free medium alone in the case of non-stimulated background cultures. Mitogens were used at the following final concentrations: 2.5 µg ml^{-1} PHA (Wellcome Research Laboratories, Beckenham, Kent), 10 µg ml^{-1} con A (Pharmacia), 20 µg ml^{-1} LPS (LPS W from *E. coli* 055:B5, Difco). The cultures were incubated at 37 °C for 44 h and then pulsed with 50 µl of ^{125}I-5-iodo-2-deoxyuridine (^{125}IUdR) (1 µCi ml^{-1}, specific activity >200 Ci mmol^{-1}, New England Nuclear Corp.) for a further 12 h. The cultures were then removed and collected using a slightly modified multiple cell culture harvester[18] (Otto Hiller Corp., Madison, Wisconsin). The cells collected on to the filter paper were rinsed with saline, 15% trichloroacetic acid and 95% ethanol before being counted in a Nuclear Chicago automated gamma-counter. Cells cultured without added mitogen contained less than 115 c.p.m. Data given are mean c.p.m. of four cultures ±s.d.

amplifying cell. Our data do not permit a precise evaluation of the half life of this activity.

Specific lymphocyte-activating determinants expressed on mouse macrophages

WHEN two populations of allogeneic lymphoid cells are cultured together, cellular interactions lead to blast transformation and proliferation of a portion of the cultured cells. In mice, this mixed leukocyte culture reaction (MLR) is under the independent control of two genetic systems: the multigenic major (H-2) histocompatibility system (MHS)[1,2] and the unigenic (non-H-2) *M* locus[3]. The nature and cellular distribution of the gene products which mediate recognition of one cell (the stimulator cell) by another cell (the responder cell) are incompletely defined. The 'recognising' structure is likely to be a specific receptor present on thymus-derived (T) lymphocytes, since T cells are generally required as responder cells in MLR[3-6]. Recently it has been possible to distinguish, from these recognition sites, gene products which are expressed on the stimulator cells[7] and which have been termed lymphocyte-activating determinants (LADs)[8]. Cell fractionation studies revealed that LADs of the MHS are expressed on both B and T lymphocytes[8,9], whereas LADs of the *M* locus are preferentially if not exclusively expressed on B lymphocytes[10]. In this study we present evidence that LADs of the *M* locus as well as LADs of the MHS are also expressed on macrophages. These genetic determinants are shown to be stable in long term cultures and to induce specific one-way reactions in mixed lymphocyte–macrophage cultures.

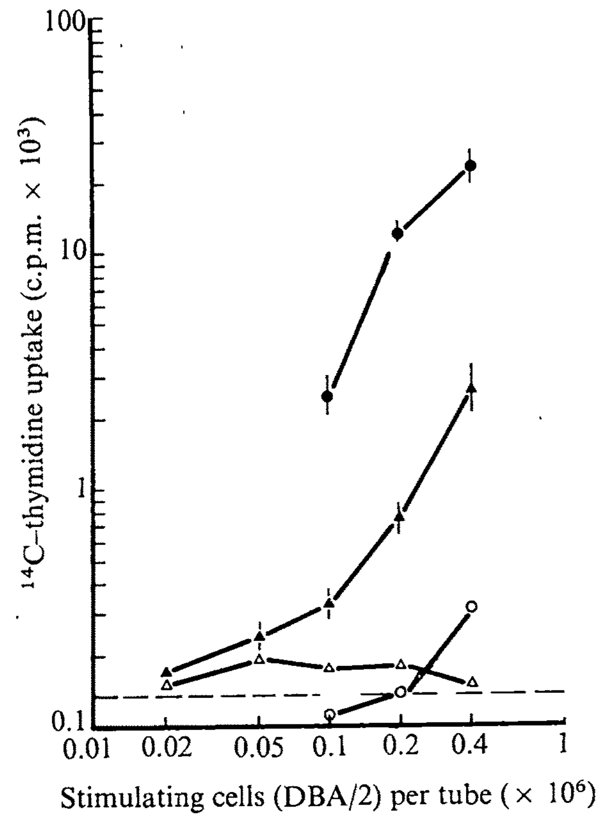

Fig. 1 Dose-response curves of mixed culture reactions with varying numbers of DBA/2 macrophages (●) or DBA/2 lymph node lymphocytes (▲) as stimulating cells and 0.6 × 10^6 BALB/c lymphocytes per tube as responding cells. Open symbols, respective stimulating cells alone. ^{14}C-thymidine uptake was measured on day 2–3. Dashed line indicates the uptake by the responding cells cultured alone.

Macrophage monolayers were prepared in flat-bottomed 9 × 44 mm polystyrene tubes using 4 × 10^5 macrophages obtained from the peritoneal cavity of normal mice (J. R.-M., V.S., F. Garrido and H.F., unpublished). After removal of non-adherent cells by several washings 6 × 10^5 lymphocytes obtained from lymph nodes of allogeneic mice were added in a total volume of 0.4 ml. These mixed cultures were incubated for 48 h at 37 °C in an atmosphere of 10% O_2, 4% CO_2 and 86% N_2. ^{14}C-thymidine (20 µl; 60 mCi mMol^{-1}) was then added and the tubes were incubated for a further 16 h. The non-adherent cells were collected on to a filter using a semi-automatic harvester and their isotope uptake measured in a liquid scintillation spectrometer.

Mouse lymphocytes cultured with allogeneic or semi-

Table 1 Proliferative response of mouse lymphocytes cultured with allogeneic or semiallogeneic macrophages

Incompatibility*	Stimulating macrophages	Responding lymphocytes	^{14}C-thymidine uptake†	Factor of stimulation‡

§ Incompatibility at H-2.

‖ Incompatibility at the *M* locus and at H-2.

allogeneic macrophages showed specific proliferative responses (Table 1). Parental lymphocytes responded well to F_1 macrophages differing either at the *M* locus or at the H-2 complex, but F_1 lymphocytes did not respond to parental macrophages. The one-way reaction in the lymphocyte–macrophage mixed cell culture system is further demonstrated by the results obtained with cells from the *H-2*^{d} identical mice DBA/2 and BALB/c. Unilateral stimulation of BALB/c by DBA/2 has been reported with lymphocytes as stimulator cells[11] and this has been attributed to the strong lymphocyte-activating determinant coded for by the *Mls*^{a} allele at the *M* locus[12]. It therefore seems that LADs of the H-2 complex as well as LADs of the *M* locus are expressed on macrophages.

The possibility that stimulation in our mixed cultures was caused by contaminating lymphocytes or polymorphonuclear cells (PMN) was excluded in various ways: (1) pretreatment of the macrophage monolayers with anti-B cell and anti-T cell serum[13] plus complement; (2) pretreatment of the monolayers with trypsin combined with extensive washing (J. P.-M., V.S., F. Garrido and H.F., unpublished); (3) preculturing the macrophages for about 10 d thus allowing PMN[14] and probably also lymphocytes to die; and (4) combining methods (2) and (3). None of these procedures reduced the stimulating capacity of the macrophage monolayers. Table 2 shows an experiment in which macrophages obtained from 10 d cultures were treated with trypsin to detach any remaining lymphocytes and to remove dead cell material, and extensively washed before they were used as stimulator cells in mixed cultures. Specific proliferative responses were again observed when the cells were incompatible at the *M* locus, at the H-2 or both.

Interestingly, *M*-locus incompatibility between lymphocytes and macrophages resulted in quite strong stimulation, whereas H-2 incompatibility only led to comparatively weak stimulation. Figure 1 shows a dose–response curve of the stimulation obtained in an *M* locus incompatible combination (DBA/2 against BALB/c). DBA/2 macrophages seemed to have stronger stimulatory capacity than DBA/2 lymphocytes. Further experiments are in progress to determine the relative stimulatory capacity of macrophages compared with other non-lymphoid or lymphoid subpopulations of cells, and to establish the genetic mapping of the LADs expressed on macrophages by testing congenic and H-2 recombinant mice.

Studies on macrophage–lymphocyte interactions in MLR date back to the early days of the MLR. Although there is general agreement that macrophages are required in the reaction, reports on their specific contribution to the allogeneic stimulus have been conflicting. Some of the results are difficult to interpret because the numbers of monocytes or macrophages were not quantitated. Wherever human purified macrophages were tested directly, they were found to be powerful stimulators of allogeneic lymphocytes[15,16]. Other non-lymphoid human cells known to carry histocompatibility antigens on their surface have usually not been found to stimulate allogeneic lymphocytes *in vitro*. In the guinea pig, macrophages were recently found to be the predominant stimulator of the MLR, far more effective than lymphocytes, fibroblasts or PMN[17]. Mouse peritoneal macrophages were found to be immunogenic not only in MLR, as described here, but also when used for induction of cytotoxic cells[18] or cells exhibiting the graft-versus-host reaction[19].

The importance of the macrophage for the immune system has recently been firmly established. Many observations suggest a function for the macrophage in antigen presentation. This may explain their requirement, for example, in soluble antigen-mediated T lymphocyte proliferation[20], MLR[21], induction of helper T lymphocytes[22] and cytotoxic effector cells[23], and in T–B cell cooperation *in vitro* leading to antibody synthesis[24]. Macrophages have also been found to be involved in the genetic control of certain immune responses[25]. Cooperation between macrophages and T cells was found to depend on a certain compatibility, which was associated with the I region, possibly with Ia antigens, of the H-2 complex (P. Erb, personal communication). Clearly, the study of macrophage cell-surface components, like Ia antigens and LADs will become increasingly important for the understanding of the nature of macrophage–lymphocyte interactions.

Control of flagellar wave movement in *Crithidia oncopelti*

MECHANISMS controlling cell behaviour are of considerable importance in biology and medicine, and much effort has been expended in experiments designed to evaluate the biochemical events which are involved in the mediation of a variety of cellular activities. Calcium ions are found to be involved in the regulation of a number of motile processes, such as muscular contraction[1], ciliary reversal[2] and cytoplasmic contraction[3]. We present here preliminary results which show that calcium may be responsible for the control of flagellar activity in a trypanasomid flagellate, *Crithidia oncopelti*. The flagellum of this organism propagates waves both distally and proximally in common with other trypanosomes[4] but in contrast to the flagella on the majority of other protozoa and spermatozoa which are observed to maintain only distally propagating waves[5]. During normal swimming *Crithidia* propagates waves from tip to base, but on meeting an obstruction wave reversal occurs for several flagellar beats, thereby causing the organism to reverse its direction of movement and enabling it to escape from the obstacle. The wave reversal thus seems to be an avoidance reaction, and can be induced by mechanical, electrical or chemical stimulation[6].

Cells of *Crithidia* have been extracted in glycerol[7] and detergent-based[8] solutions in such a way that the addition of ATP and magnesium to the preparation induces wave motion. The character of the reactivated flagellar movements is critically dependent on a number of physical and chemical factors during extraction and reactivation; with the detergent-based technique higher flagellar beat frequencies are obtained than for corresponding conditions with the glycerol-based method. In a previous report on the behaviour of glycerol-extracted cells[7] the wave direction was from the basal end of the flagellum only, which seemed to have lost the ability to reverse the direction of wave propagation. In those experiments, however, no attempt was made to control the concentration of calcium ions, which we have now found to have a significant effect on the behaviour of the system.

In our experiments the reactivating solutions contained ATP and magnesium at a concentration of 1 mol m^{-3} (1 mM) and the concentration of free calcium in the solutions was controlled by the addition of EGTA. The amount of calcium in the solutions was determined using an atomic absorption spectrometer, and the concentration of free calcium ions was calculated using a method described previously[8]. Unless the calcium concentration was low in both the extraction and reactivation solutions, waves are propagated from the base of the flagellum only. When the concentration of calcium is maintained below about 10^{-4} mol m^{-3} (10^{-7} M), waves propagate from tip to base immediately after reactivation, but reverse after a time, which depends on the preparative technique. Using a procedure based on glycerol, tip-to-base propagation was observed for about 20 min and occasional reversal was seen during this time. Extraction and reactivation with detergent-based solutions produced waves which propagated from the tip for a period of between 2 and 4 min; no reversal was observed during this time. Electron microscopy shows that the glycerol-extracted preparations have fragments of membrane associated with the axonemal structure whereas the cells extracted with detergent have no visible membrane.

The effect of calcium ions on flagellar activity has also been investigated using ionophores, X537A and A23187, known to transport divalent ions across membranes[9]. With cells *in vivo*, the presence of either of the ionophores and 1–5 mol m^{-3} (1–5 mM) $CaCl_2$ caused the majority of organisms in a sample to propagate waves from base-to-tip—that is, in the opposite direction to that normally expected of the cells *in vivo*. When EGTA was added to the medium instead of $CaCl_2$ a few organisms propagated waves from base-to-tip but the majority maintained proximally directed waves. When ionophore, $CaCl_2$ or EGTA were added separately to a suspension of the organisms, in the concentrations used during the experiments, they caused no abnormal flagellar movements.

These results suggest strongly that calcium ions are able to control the direction of flagellar wave propagation in the preparations of *Crithidia* used. Note that the experiments described here were performed on *in vitro* systems and that the control mechanism may be different in the living cell. Nevertheless many features of the motility of the systems used are similar to those of the living organism and it is tempting to speculate that adjustment of the calcium concentration in the living cell is used to alter the direction of propagation of the flagellar waves.

The behaviour of the systems studied favours the idea that the membrane is intimately involved in the control mechanism in *Crithidia*, as suggested previously[4]. In those preparations in which the membrane is completely dissolved, namely the detergent-extracted systems, proximally directed wave propagation occurs for a few moments only after reactivation. The other systems studied are known to have residual membrane structures, although for the glycerol-extracted preparation the membrane is considerably disrupted, and show wave propagation from tip-to-base for considerable periods of time, with occasional wave reversal. A possible interpretation of these results is that in a living cell the membrane acts as a receptor for extracellular events and regulates the intra-flagellar calcium concentration, which, in turn, controls the reaction determining the direction in which waves will be propagated. An alternative explanation of the difference in behaviour between the detergent- and glycerol-extracted cells is that, in the latter case, preservation of the complete motile system is sustained for a longer period. It is well known that glycerol acts as a preservative for spermatozoa with similar axonemal structures to that of *Crithidia*, whereas detergents solubilise protein structures.

The site of calcium activity and sequestration within the flagellum is a matter for speculation at present, but a reasonable suggestion can be made with reference to the currently favoured sliding filament hypothesis[10] of flagellar activity, according to which the forces required to bend a flagellum originate in active relative sliding of the outer doublet microtubules of the axoneme. The ability to alter the direction of wave propagation in *Crithidia* implies that, for this organism at least, the relative direction of active filament sliding can be reversed. If the sliding is induced by swinging movements of linkages between the outer tubules of the flagellar axoneme it is possible that the effect of calcium is to regulate the direction in which a link will swing. If this is the case the close association of the membrane and the outer axonemal tubules would enable a stimulus originating at the membrane to be transferred quickly to the site of active force development in the organelle. It is possible that the flagellar membrane acts as the storage site for calcium ions, so that the appropriate stimulus could cause the release or sequestration of ions by the membrane, thus causing the appropriate reversal of flagellar bend movement.

Calcium has been found to have an effect on the behaviour of two other systems which carry organelles with the same 9+2 axonemal structure of the *Crithidia* flagellum. In chemically extracted *Paramecium*, ciliary reversal, which is an avoiding response *in vivo*, can be induced by raising the concentration of external calcium[2]; these observations support Naitoh's[11] view that ciliary activity in the organism is controlled by two physiological systems each of which utilises ATP. One system, activated by magnesium, is responsible for bending the cilia, whereas the other, calcium-activated, determines the direction of beating. The mechanisms of ciliary reversal could be the same as that of wave reversal in *Crithidia*, since the two activities may result from a changed sliding direction of the outer tubules. Thus, like *Paramecium*, *Crithidia* may have separate systems for propagating bends and for initiating the avoiding response, both deriving energy from ATP hydrolysis, with the former activated by magnesium and the latter by calcium.

The other system referred to is the sea urchin spermatozoa, the flagellar waveforms of which can be altered by varying the calcium concentration[12]. We have found that in addition to controlling the direction of flagellar beating, variations in the calcium concentration cause modifications in the wave shape of the flagellum of *Crithidia*. This may bear a relationship to the behaviour of sea urchin spermatozoa but we have insufficient information at present to make a detailed comparison between the two. Further experiments are in hand to quantify the effects of calcium on motility and to locate the sites of activity and sequestration of this ion within the flagellum.

We thank Roche Products Ltd, and Lilly Research Centre Ltd, for respective gifts of ionophores, X537A and A23187. This work was supported in part by a grant from the SRC. We also thank Dr M. Hughes for discussion and for assistance with the operation of the atomic absorption spectrometer.

Comparison of doubling numbers attained by cultured animal cells with life span of species

HUMAN fibroblasts in culture undergo 40–60 cell doublings (indicating numbers of cell generations) before the growth rate declines and death of cells ensues[1]. Hayflick[2] has suggested that the final doubling numbers achieved by cultured diploid cells may be related to the life span of the animal species from which the cells were derived. This suggestion is based on reported final doubling numbers for human, chicken and mouse being in the ranges 40–60, 15–35, and 14–28, whereas the maximum life span of each of these species was 110, 30 and 3.5 yr, respectively. We report here findings on final cell doubling numbers attained when cells from ten different animal species were serially subcultured. Tissues of foetal or newborn origin were used to initiate cultures from man, horse, monkey, cat and dunnart, and the cultures of wallaroo × red kangaroo hybrid, kangaroo, wallaby, rabbit and potoroo, were derived from adult tissues.

After reaching appropriate cell doubling numbers (Table 1) cell cultures derived from man, horse, wallaroo × kangaroo hybrid, kangaroo, wallaby and potoroo showed a decline in growth rate and an increase in cell granularity that could be compared with the characteristics described by Hayflick[1] as Phase III in the growth of human diploid cell strains. There was no evidence that technical procedures or infection with mycoplasmas or viruses caused this decline and final death of cultures. In the case of monkey, cat and rabbit, the cells continued to grow after the doubling numbers listed in Table 1 but counts after this time showed that there had been a shift from a diploid to a heteroploid chromosome constitution. There was no change in the growth rate or morphology of these cells at this time On last examination, the cultures from monkey, cat and rabbit had reached 100, 100 and 70 cell doublings respectively. On the other hand, the dunnart culture when last examined after 170 cell doublings had shown no change in growth rate and no change from the diploid chromosome pattern.

In our studies, the final cell doubling number for their diploid cells in the species listed cannot be related to their life spans. This applies to those which remained diploid throughout their lifetime and to those which subsequently became heteroploid. Note that these doubling numbers are based on only one culture series for each species. The final cell doubling number attained by each species may well be found to be higher when cells are cultured from a large number of individuals within one species, as experience with diploid cells cultured from a large number of human embryos has shown the final doubling number to be in the range 40–60. Adult tissues were used to initiate five of the cultures. In extensive studies on human tissues ranging in age from foetal to 90 yr, Martin *et al.*[7] showed that final doubling numbers decreased by 0.2 population doublings per year of donor life. We may therefore have obtained higher final doubling numbers for wallaroo × red kangaroo hybrid, kangaroo, wallaby, rabbit and potoroo if foetal tissue had been used, thus making the association between life

Table 1 Comparison of doubling numbers

Species	Maximum lifespan (yr)	No. of doublings attained by diploid cells	Tissue of origin of cells
Human, *Homo sapiens*	110[4]	60	Lung
Horse, *Equus caballus*	46[5]	82	Kidney
Monkey, *Macaca speciosa*	34[5]	60	Lung
Cat, *Felis cattus*	28[5]	92	Lung
Wallaroo, *Macropus robustus robustus* × Red kangaroo hybrid, *Megaleia rufa* Hybrid	19[5]	65	Skin*
Grey kangaroo, *Macropus gigantus*	16[5]	46	Skin*
Pretty-faced wallaby, *Macropus parryi*	16[5]	46	Heart*
Rabbit, *Oryctolagus cuniculus*	13[5]	70	Skin*
Potoroo, *Potorous tridactylus*	7[5]	40	Heart*
Fat-tailed dunnart, *Sminthopsis crassicaudata*	3[6]	170	Skin

* Cell lines derived from adult tissue. Other lines derived from foetal or newborn tissue. Cultures were initiated from small pieces of tissue from various sites. Growth medium was Basal Medium Eagle's (BME)[3] plus 10% foetal calf serum. Cultures from all species showed a fibroblast-like morphology, which persisted throughout the experiments, and were subcultured when confluent (within the range 4–7 d). Most cultures were divided 1:4 at subculture. Rabbit and dunnart cells grew more rapidly and could be divided 1·8 or 1:16, whereas the cultures derived from kangaroo grew more slowly and were divided 1:2. Chromosome examinations were made at regular intervals on all cell cultures to ensure that the normal diploid number of chromosomes was present.

spans of species and the final doubling numbers of their cultured cells more obscure.

Heat-labile enzymes in Werner's syndrome fibroblasts

Recent reports indicate[1,2] that cultured skin fibroblasts from subjects with Werner's syndrome, a hereditary disease of premature ageing[3], have an increased proportion of heat-labile glucose-6 phosphate dehydrogenase (G-6PD) compared with normal cells undergoing ageing *in vitro*[1,2,4]. Additionally, two HL-A antigens show profoundly altered reactivities with specific antisera[2], which in total demonstrates that three diverse gene products are markedly abnormal in Werner's fibroblasts. The purpose of our study was to document further this phenomenon in Werner's cells. We now report a high heat-labile fraction of 6-phosphogluconate dehydrogenase (6-PGD), an enzyme involved in the hexose monophosphate shunt, and hypoxanthine–guanine phosphoribosyltransferase (HGPRT), an enzyme concerned with purine metabolism.

Table 1 Heat-labile fraction of enzymes in cultured fibroblasts from a subject with Werner's syndrome and controls

	% Heat-labile enzyme	
	6-Phosphogluconate dehydrogenase	Hypoxanthine–guanine phosphoribosyltransferase
Werner's syndrome		
Experiment 1	14	50
Experiment 2	24	36
Experiment 3	—	40
Controls		
Early passage	0.80±0.43 (*n* = 10, range 0–4)	7.66±1.70 (*n* = 9, range 0–14)
Late passage	4.89±1.16 (*n* = 12, range 0–9)	24.43±2.84 (*n* = 7, range 15–32)

Werner's cells were within 3–6 mean population doublings (MPD) of termination in a total replicative life span of 18 MPD; the limited number of experiments was dictated by the poor growth of these cells and finally exhaustion of their supply. Control values (mean± s.e.m.) represent experiments on strains of cultured cells from five normal donors aged 27–76 yr. Early passage cells were in the first third of their replicative life spans whereas late passage cells were within 0–9 MPD of growth termination (range of life spans 44–70 MPD). Werner's values are significantly different from late passage controls, $P < 0.01$. Controls at late passage were significantly different from early passage controls, $P < 0.01$.

Cultures were derived and propagated as described previously[2]. The assays for 6-PGD and HGPRT and the estimates of heat lability, which were accurate within 3–4%, were carried out as before[4,7]. Control strains were studied at early and late passage, the latter serving as more suitable controls for the poorly growing Werner's cells.

Table 1 indicates that normal fibroblasts accumulated an increased fraction of heat-labile 6-PGD and HGPRT during the culture life span. But Werner's cells clearly contained a higher proportion of heat-labile enzyme, even when compared to control fibroblasts at late passage. Mixing experiments with equal parts of crude extracts from Werner's and control strains gave approximately intermediate heat-labile fractions suggesting that neither proteolysis nor a deficiency of stabilising factors was responsible for the results observed in Werner's cells[1,2,4,7]. The high heat-labile fraction of HGPRT in late-passage controls considerably exceeds that of 6-PGD and previous data on G-6PD[1,2] for reasons that are uncertain but which probably relate to loss of the stabilising cofactor during the dialysis performed before HGPRT assay[7].

The data indicate that 6-PGD, an enzyme coded for by an autosomal gene and the X-linked HGPRT[7] are markedly abnormal in Werner's fibroblasts at the same time as alterations appear in G-6PD and HL-A antigens, genetic loci that are also X-linked and autosomal, respectively[6,7]. The results also show an increasingly defective fraction of 6-PGD and HGPRT in normal cells during ageing *in vitro*, as was found earlier for 6-PGD and G-6PD[1,2,4,7,8]. Indeed, similar abnormalities of the identical gene products have now been demonstrated in cultured cells derived from subjects with progeria, a related disorder of premature ageing[5-8]. The molecular nature of these defects is unclear and may even be unique in each case[7,8]. It is also not certain whether defective proteins are the consequence rather than the cause of cellular ageing. But these observations taken together with the decreased replicative potential that occurs during normal ageing[6,9,10] and the more severe growth limitation observed in Werner's and progeria fibroblasts[6,10], strengthen the view that the rate of fibroblast ageing *in vitro* is directly related to the rate of ageing *in vivo*[1,2,4-10].

Morphine abstinence is associated with increased brain cyclic AMP

The finding that theophylline, which inhibits brain cyclic AMP phosphodiesterase[1], produces a "quasi-morphine abstinence syndrome" that is intensified by naloxone and suppressed by heroin[2] suggested that the real morphine abstinence syndrome may be associated with increased activity of a brain cyclic nucleotide. A suitable phosphodiesterase inhibitor would therefore heighten and a stimulant of phosphodiesterase would lower the intensity of real morphine abstinence signs. To test this, we administered such drugs to morphine-dependent rats shortly before withdrawal was precipitated with naloxone, so that the drugs would act only during the expression of abstinence. As these experiments indicated that the abstinence syndrome is largely associated with increased cyclic nucleotide activity, we attempted to identify the nucleotide by intracerebroventricular injection of cyclic nucleotides. These experiments indicated that cyclic AMP rather than cyclic GMP was primarily involved.

Opiate dependence was induced in male white Wistar rats (100–150 g) by a single subcutaneous injection of morphine, 150 mg kg^{-1}, in a sustained-release preparation[3]. Withdrawal was precipitated 24 h later with 0.1 or 1 mg kg^{-1} subcutaneous (s.c.) naloxone hydrochloride in 0.9% w/v saline. To modify withdrawal effects, imidazole (which stimulates phosphodiesterase[4], including that of rat brain[5]), theophylline or caffeine[1] was given orally in water 2 h before naloxone challenge; or 3-isobutyl-1-methylxanthine (IBMX), which inhibits cyclic AMP phosphodiesterase of rat brain (A. C. Roy, personal communication), guinea pig brain[6] and mouse neuroblastoma cells[7], was given subcutaneously in saline, 1 h before challenge. Alternately, cyclic AMP, cyclic GMP or the dibutyryl derivative of each, dissolved in sterile saline, was injected into the left lateral cerebral ventricle of the brain through an indwelling cannula[8], 0.5 or 1 h before challenge. After challenge with naloxone or saline, behavioural responses were recorded by observers who did not know what treatment each animal had received. Because the incidence of abstinence effects is related to the cage in which the animal is situated, rats were observed individually, either in plastic buckets, in which jumping was the predominant abstinence effect; or, for other behavioural responses, in low cages that suppressed jumping. Jumps were counted, and other withdrawal signs were recorded as present or absent. The significance of differences between jumping scores, and between total scores for the abstinence syndrome as a whole, were tested by the Mann–Whitney *U* test[9], adapted for the computer[10]. For quantal counts, Fisher's Exact Probability Test[9] was used.

As jumping was a characteristic and readily quantifiable sign of opiate abstinence, we tested how far drugs that modify brain phosphodiesterase activity affected the jumping of dependent rats when abstinence was precipitated with the higher dose of naloxone (1.0 mg kg^{-1}). Table 1 shows that much jumping occurred in rats that had received sustained-release morphine, followed by a phosphodiesterase inhibitor and naloxone. When either morphine or phosphodiesterase inhibitor was omitted from the treatment schedule, jumping was markedly reduced. Imidazole, in dependent rats, significantly decreased jumping and overcame the ability of theophylline to increase jumping.

These results suggested that this expression of abstinence was associated with an increase in brain cyclic nucleotide. To identify the nucleotide, we administered cyclic AMP, cyclic GMP or one of their dibutyryl derivatives into the left lateral cerebral ventricle of morphine-dependent rats and observed jumping after precipitating abstinence with naloxone (1.0 mg kg^{-1}). Intracerebroventricular injection of cyclic AMP and, to a lesser extent, dibutyryl cyclic AMP significantly increased jumping (Table 1). Cyclic GMP did not do so, although dibutyryl cyclic GMP increased jumping to an extent that approached statistical significance ($P = 0.052$). Dibutyryl cyclic GMP, however, significantly decreased two abstinence signs, teeth chattering ($P < 0.05$) and chewing ($P < 0.01$). That these were the two signs that IBMX also significantly lessened at 5–7 min after challenge (see below) suggested that

Table 1 Effects of cyclic nucleotides or of drugs inhibiting or stimulating phosphodiesterase on naloxone-precipitated jumping in morphine-dependent rats

Median total score*	2	3	5^{ab}	6	8^{d}

All rats were treated subcutaneously with 150 mg kg^{-1} morphine (M) in a sustained-release preparation, or with vehicle (V) and, 24 h later, all were challenged with naloxone (N; 0.1 mg kg^{-1} subcutaneously). In the experiment with IBMX, three groups, each of 15 rats, received 1 h before challenge, either IBMX (I; 10 mg kg^{-1} s.c.) or vehicle, and responses were recorded during 15–17 min after challenge. In the experiments with cyclic nucleotides, groups totalling 21 and 23 rats received respectively into the left lateral cerebral ventricle, 0.5 h before challenge, either saline (V) or 50 µg cyclic AMP (A) and responses were recorded during 15 min after challenge.

Letters a–e in the body of the table indicate comparisons between columns where a significantly greater incidence was found; where the letter is italic, $P < 0.01$; where it is not, $P < 0.05$.

*The significance of the difference between intensities of the abstinence syndrome as a whole was based on the median total scores.

NT, Not tested or not recorded.

some increase in cyclic GMP, induced by inhibition of phosphodiesterase, may be part of the pattern of the quasi-abstinence syndrome, but that cyclic GMP contributes little to the real abstinence syndrome, in which both of these signs are prominent (Table 2, column d).

Certain drugs, such as atropine, which interfere with neurotransmitters inhibit some abstinence signs in the rat, but intensify others, whereas heroin lessens the incidence of all signs[3]. To determine how closely the substances under investigation were related to the generation of the abstinence syndrome as a whole, we studied the extent these substances affected other abstinence signs, as well as jumping. Three groups, each of 15 rats, received either sustained-release morphine or vehicle; 23 h later each group received IBMX or vehicle; and at 24 h, all were challenged with the lower dose of naloxone (0.1 mg kg^{-1}), and the presence of abstinence signs was recorded during two 2 min observation periods. When responses were recorded 5–7 min after challenge, irritability to touch ($P < 0.05$) and handling ($P < 0.001$), rearing ($P < 0.001$) and restlessness ($P < 0.001$) were significantly increased by IBMX; but teeth chattering ($P < 0.05$) and chewing ($P < 0.025$) were significantly reduced. At 15–17 min after challenge, however, six of the twelve individual abstinence signs were significantly increased by IBMX (Table 2, columns b and c). IBMX also increased the intensity of the abstinence syndrome as a whole ($P < 0.002$).

In two experiments, to test whether cyclic AMP increased other abstinence signs, as well as jumping, rats received sustained-release morphine and 23.5 h later, an intracerebroventricular injection of either 50 µg cyclic AMP or saline. Half an hour later, all rats were challenged with 0.1 mg kg^{-1} naloxone and the occurrence of behavioural responses, other than jumping, was recorded. The incidence of body shakes ($P < 0.05$) and head shakes ($P < 0.025$) was significantly greater after cyclic AMP (ten rats) than after saline (nine rats). In a second experiment, the incidence of ptosis ($P < 0.025$) and of ejaculation ($P < 0.05$) was significantly greater in the cyclic AMP group (13) than in the saline group (12). None of the responses was significantly greater in the saline controls in either experiment. Table 2 (columns d and e) gives the pooled results of these two experiments, in which irritability to touch was also significantly greater in the rats receiving cyclic AMP. In these rats, also, the intensity of the abstinence syndrome as a whole was significantly greater ($P < 0.001$). In the first of these two experiments, a third group (nine rats) showed that intracerebroventricular cyclic GMP was no more effective than saline. After cyclic AMP, the abstinence syndrome as a whole was more intense ($P < 0.05$), and the incidence of body shakes ($P < 0.005$) and of ejaculation ($P < 0.05$) was greater, than after cyclic GMP.

As inhibitors of phosphodiesterase intensified abstinence effects, we tested whether naloxone inhibited this enzyme. At concentrations up to mmol l^{-1}, however, naloxone did not inhibit cyclic AMP phosphodiesterase in rat brain homogenate (A. C. Roy, personal communication).

Our experiments show that drugs modifying the activity of brain cyclic AMP phosphodiesterase largely modify inversely the intensity of morphine abstinence effects. Thus the intensity of such effects can probably be associated with the level of cyclic nucleotide in brain cells. Injection of cyclic AMP intracerebroventricularly intensified several abstinence signs, without significantly diminishing any, whereas cyclic GMP reduced some of these signs, without significantly increasing any. Moreover, cyclic AMP intensified the abstinence syndrome as a whole, but cyclic GMP did not. These results argue that increase in cyclic AMP in appropriate brain neurones is associated with the generation of the morphine abstinence syndrome.

Reports on the relationship of abstinence effects to cyclic AMP in precipitated opiate withdrawal are consistent with our findings. Thus, a direct association was observed between whole brain cyclic AMP content and the intensity of the precipitated abstinence syndrome in morphine-dependent rats[11]. Also, cyclic AMP, administered to dependent mice, intensified the weight loss, although not the jumping, of precipitated abstinence[12]. These observations, coupled with our experimental findings suggest that opiate dependence is a state of potential increase in activity of a neuronal cyclic AMP mechanism, held in check by the presence of opiate, which inhibits an adenyl cyclase of morphine-sensitive neurones[13-15].

We thank Dr W. A. Klee, Mr A. C. Roy, Dr S. A. Saeed and Mr C. Schneider for helpful discussions; Mr M. A. Collins, Mr N. J. Cuthbert, Miss J. F. de C. Sutherland, Miss L. A. Taylor and Mr C. M. Tobin for observing animals, Mr L. C. Dinneen for statistical advice and Sankyo Limited for naloxone.

Impulse-flow regulation of high affinity choline uptake in brain cholinergic nerve terminals

ACETYLCHOLINE (ACh) synthesis is coupled, in some unknown manner, to ACh release caused by neuronal impulse flow[1–4]. Accordingly, several models have been proposed regarding the regulation of ACh synthesis. These include feedback competitive inhibition of choline acetyltransferase by ACh[5,6], and mass action regulation of choline acetyltransferase[7]. More recently, high affinity choline uptake, which is very localised to cholinergic nerve terminals[8], has been proposed as a regulatory step in ACh synthesis[9–12]. If high affinity choline uptake were coupled to ACh synthesis and release, then one would expect changes in the high affinity choline uptake system after alterations in synthesis and release. We have found changes in the high affinity choline uptake system in hippocampal synaptosomes after treatments which alter neuronal impulse flow to cholinergic nerve terminals.

The rat hippocampus was used because of its known cholinergic innervation from the septum[8], and because of the possibility of altering neuronal impulse flow in this tract[4,13]. We used two means of slowing and/or stopping impulse flow. These were intraperitoneal injection of pentobarbital, and placement of acute radio frequency lesions in the septum under ether anaesthesia[13,14]. The evidence that pentobarbital stops or slows impulse flow has been summarised and supported recently[13]. Placement of acute lesions would stop impulse flow by interrupting the axons. In pentobarbital-treated animals we have reversed the cessation of impulse flow by electrical stimulation of the medial septal area[4].

A kinetic analysis of the high affinity choline uptake into hippocampal synaptosomes from untreated control animals revealed K_m and V_{max} values of about 0.8 μM and 60 pmol per 4 min per mg protein respectively (Fig. 1, Table 1). These values are similar to those obtained by other workers[9–11,15]. A similar analysis using synaptosomes from animals pretreated with pentobarbital (30 min) or septal lesions (1 h) revealed a decreased V_{max} (40%) with no change in the apparent K_m. When impulse flow to the hippocampus was restored in pentobarbital-treated animals by stimulating the septum for 10 min, the pentobarbital-induced reduction in V_{max} was reversed and the kinetic parameters returned to untreated control values (Fig 1, Table 1). These kinetic changes were observed in every experiment (range of reduction in V_{max} in individual experiments was 30–65%). Complementary to the above changes, we have found that administration of scopolamine, an anticholinergic drug which would increase ACh turnover, and pentylenetetrazol, a central nervous system stimulant, results in a 25–50% increase in choline uptake.

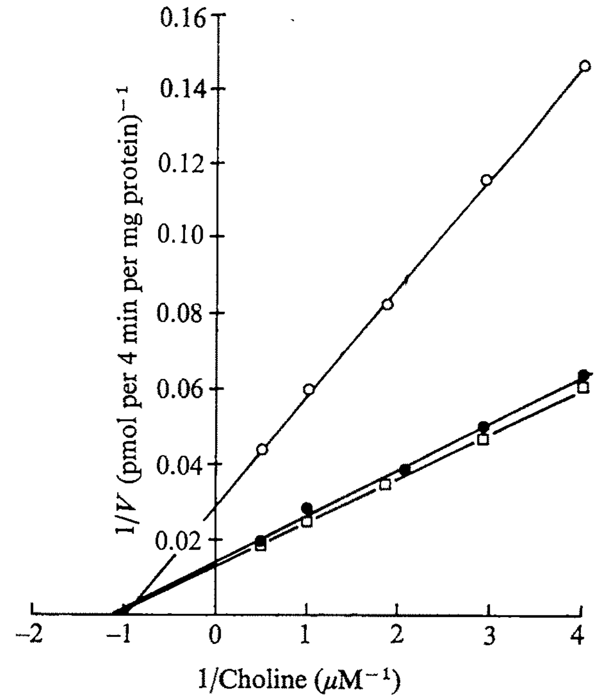

Fig. 1 Lineweaver–Burke analysis of high affinity choline uptake into hippocampal synaptosomes from untreated control rats, pentobarbital (65 mg kg^{-1}) treated rats, and electrically stimulated pentobarbital-treated rats. Male Sprague-Dawley rats (175–225 g) were administered pentobarbital intraperitoneally and decapitated 30 min later. Electrical stimulation[4] (40 Hz, 200 μA) was begun 20 min after injection, and continued for 10 min. Animals were decapitated 7–10 s later. In all experiments, the hippocampus (whole, bilateral hippocampal formations) was dissected rapidly and homogenised in 20 volumes of 0.32 M sucrose. Crude mitochondrial fractions were isolated by differential centrifugation and resuspended in the original volume of 0.32 M sucrose. Samples (100 μl) of this suspension were added to 0.9 ml of Krebs–Ringer solution, and incubated at 30° C for 4 min for uptake measurements[12,14]. Blank values were obtained by maintaining parallel samples at 0–2 °C. Choline concentrations added to the incubation media varied from 0.2 to 2 μM. Higher concentrations were not used because uptake by the low affinity component would tend to predominate[15]. Lines were fitted to the data points by least squares analysis. ○, Pentobarbital; ●, control; □, pentobarbital + stimulation.

No inhibition of uptake into synaptosomes from untreated animals was observed when 10^{-3} M pentobarbital was added directly to the incubation medium during the uptake process. Administration of pentobarbital to rats had no effect on the uptake of low concentrations of ^{3}H-glutamate or ^{3}H-tyrosine by hippocampal synaptosomes, indicating that the reduction in choline uptake was not a nonspecific effect on synaptosomal uptake in general. Since there are large post-mortem increases in choline levels[16], it seemed possible that the changes in V_{max} observed here could have been caused by isotopic dilution of labelled choline by endogenous choline, which may be produced to a greater extent in pentobarbital-treated and lesioned animals than in controls. When endogenous choline levels in the media were measured after incubation, however, they were extremely low and no difference was found between synaptosomal fractions from pentobarbital-treated animals and those from control animals. It also seemed possible that our results could have been caused by an increased efflux of ^{3}H-choline or ^{3}H-ACh from synaptosomes from treated animals, rather than by a decreased uptake. But, the efflux of radioactivity from resuspended, prelabelled synaptosomes (prepared for routine uptake) from treated or control animals showed no differences. The reversal of the pentobarbital effect on V_{max} by stimulation was restricted to the hippocampus, and occured in no other brain regions. This indicates that the reversal was dependent on anatomical connections for carrying the impulses and was not caused by nonspecific effects of surgery.

The effect of pentobarbital administration on the low

Table 1 Alterations in high affinity choline uptake into rat hippocampal synaptosomes

Treatment	K_m(μM)	V_{max} (pmols per 4 min per mg protein)
None	0.76 ± 0.08 (5)	59.8 ± 4.0 (5)
Acute septal lesion	0.84 ± p.04 (4)‡	35.8 ± 24 (4)*
Pentobarbital	0.95 ± 0.08 (5)‡	38.4 ± 2.9 (5)†
Pentobarbital + septal stimulation	0.75 ± 0.03 (5)‡	59.6 ± 3.6 (5)‡

See legend to Fig. 1 for experimental details. Values are mean ± s.e.m. (*n* = number of experiments.)

* 40% reduction compared with untreated controls, $P < 0.05$.

† 36% reduction compared with untreated controls, $P < 0.025$.

‡ No significant difference compared with untreated controls.

Acute septal lesions were placed under ether anaesthesia so that anaesthetic was not present at time of death. Sham lesioned animals did not have a reduced synaptosomal uptake of choline.

affinity uptake[15] of choline was also examined. With high concentrations of ^{3}H-choline in the medium (20–150 μM), when most uptake would be by the low affinity system[15], only a slight decrease (5–10%) in uptake velocity was observed in hippocampal synaptosomes derived from pentobarbital-treated animals. This change, however, could be explained on the basis of the presence of the high affinity uptake component, which would still account for a significant fraction of the choline accumulated, even at these higher concentrations[15]. Thus, these impulse flow-dependent changes in choline uptake are probably restricted to the high affinity system which is highly localised to cholinergic nerve terminals[8].

While these data demonstrate an impulse-flow regulation of the accumulation of choline by cholinergic terminals, it is difficult to distinguish if the impulse-flow regulation acts primarily on the uptake mechanism or secondarily after some other regulatory change. This is because one cannot clearly separate choline uptake from subsequent acetylation of choline, that is, there is no inhibitory drug or simple treatment to block acetylation without also inhibiting uptake On the other hand, uptake seems to be primarily affected. We have examined choline acetyltransferase in the absence of uptake, that is, in its soluble state, and have found no change in its kinetic properties with regard to substrate or cofactor This situation is in contrast to that with the dopamine-containing neurones where kinetic changes are found in soluble tyrosine hydroxylase after changes in impulse flow[17]. Also, when we examined the synaptosomal content of ^{3}H-choline and synthesised ^{3}H-ACh from control and treated animals, we found a similar ratio of these componds in both cases. Thus the reduction in uptake after treatment could not be explained solely by reduced conversion of choline to ACh. Also, the reduction in uptake after treatment is only observed when synaptosomes are incubated in the presence of sodium ion; this reflects the involvement of the high affinity uptake system which is highly sodium dependent[9,15].

Since the molecular mechanisms underlying choline uptake are unknown, we do not know how the observed changes in V_{max} occur. Because the change is in uptake velocity rather than affinity, it may be that the net result of reducing impulse flow is to either partially immobilise or slow the presumed choline carrier. Since choline uptake is dependent on ions, most notably sodium[9,15], changes in ionic fluxes across the membrane during impulse flow may in some way be responsible for the regulatory influence.

The results presented here show that changes occur in the high affinity choline uptake system after treatments which alter the activity of cholingeric neurones. The reduction in V_{max} in conditions where impulse flow is presumably stopped or slowed, and its increase after stimulation, would have functional significance in that the high affinity choline uptake system would respond to the need of the neurone for formation of releasible ACh. This possibility receives additional support from experiments with perfused ganglia where nerve stimulation accelerates choline uptake by cholinergic terminals[18,19]. These results provide strong support for the view that choline uptake is rate-limiting[9–12] and regulatory in the synthesis of ACh.

Dopamine-like effects of cholera toxin in the central nervous system

IT is now well established that cyclic AMP acts as an intracellular 'second messenger' in mediating the effects of several hormones on their target cells[1]. The hypothesis that cyclic AMP serves a similar function in mediating the effects of certain neurotransmitters in the central nervous system (CNS) has received some support[2,3]. For example, the neurotransmitters noradrenaline and dopamine stimulate the synthesis of cyclic AMP in tissue slices or homogenates of brain regions innervated by neurones which use these transmitters[4–6]. Further, the actions of these transmitters on neural firing when applied by iontophoresis can be mimicked by cyclic AMP[2]. Bilateral injections of small amounts of dopamine into the nucleus accumbens of rats stimulates locomotor activity[8]. In the present experiments small amounts of cholera toxin were injected bilaterally into the nucleus accumbens of rats and the time course of its effects on adenylate cyclase and locomotor activity were determined. The only known mechanism of action of cholera toxin (choleragen) is activation of adenyl cyclase[7] in intact cells subsequent to its binding to a cell-surface receptor, the ganglioside GM$_1$ (refs 9–11). The results support the hypothesis that dopaminergic transmission in the CNS is mediated by cyclic AMP.

Cannulae were implanted bilaterally into the nucleus accumbens septi (NAS) of adult male Sprague–Dawley rats and choleragen (1 μg in 1μl) or 1 μl of vehicle was injected. To distinguish between possible pre- or postsynaptic effects of the toxin on dopaminergic mechanisms, a further group of animals was prepared which had selective bilateral lesions of the dopamine terminals in the nucleus accumbens induced

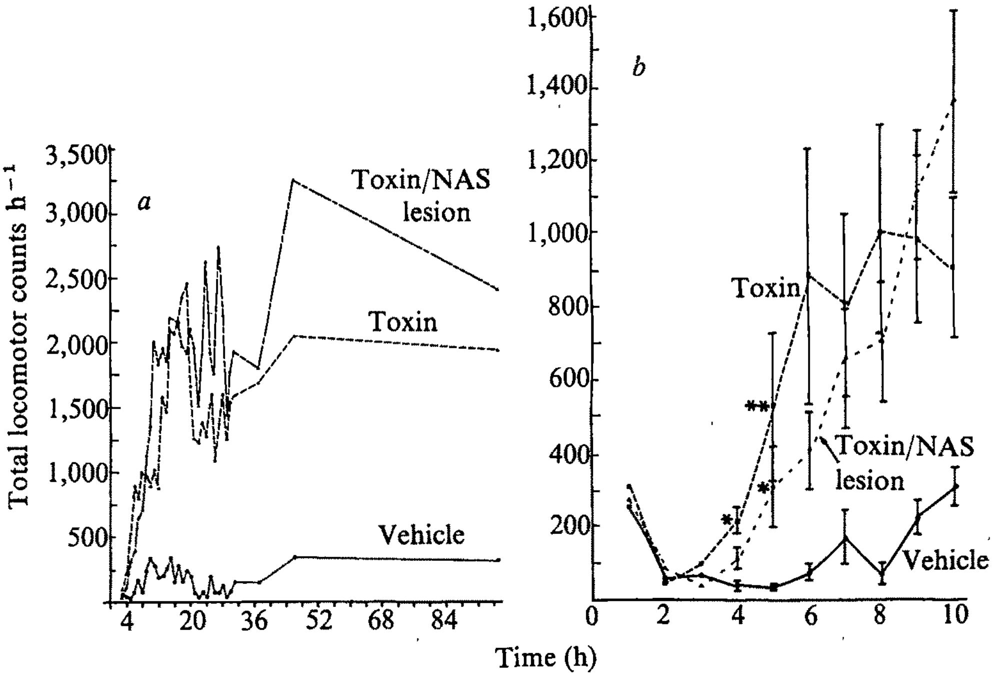

Fig. 1 *a*, Effect of choleragen on locomotor activity. Three groups of six adult male Sprague–Dawley albino rats were used. One group (Toxin) received bilateral injections of choleragen (1 μg in 1 μl) into the nucleus accumbens. Another group (Vehicle) was similarly treated with injections of vehicle solution (0.125 M Tris-HCl, *p*H 7.4, containing 0.05 M NaCl and 0.00025 M EDTA). A third group (Toxin/NAS lesion) had been previously treated with 6-hydroxydopamine (8 μg in 2 μl) injected one month previously bilaterally into the nucleus accumbens to destroy the dopaminergic innervation before toxin treatment. Toxin was prepared according to the method of Finkelstein and Lo Spalluto[15]. Injections of choleragen or vehicle were made at a rate of 1 μl min^{-1} through 30 gauge stainless steel tubes inserted into chronically implanted guide cannulae (23 gauge stainless steel) which had previously been stereotaxically implanted in the NAS. Locomotor activity was measured in a bank of wire cages each with two horizontal photocell beams along the long axis. One animal was placed in each cage. The number of photocell beam interruptions per hour was recorded at hourly intervals for 30 h. Thereafter the animals were replaced in their home cages. Locomotor activity was recorded intermittently for a further period of 14 days. *b*, Shows an expansion of the first 10 h of (*a*). Locomotor activity in the toxin-treated groups becomes significantly activated above control activity at the fourth and fifth hours after choleragen injection. $^{*}P<0.05$, $^{**}P<0.01$.

by 6-hydroxydopamine injections (8 μg in 2 μl) one month before choleragen administration. This procedure reduces nucleus accumbens dopamine concentration to approximately 20% of control, whereas striatal dopamine is not affected (P. H. K., P. Seviour, and S. D. Iversen, in the press). These animals also had cannulae bilaterally implanted and received choleragen (1 μg in 1 μl) bilaterally After injection rats were placed in individual photocell cages and locomotor activity recorded every hour for the first 36 h and then at periodic intervals. No effect was seen for the first 3 h, after which time locomotor activity in the lesioned and non-lesioned groups of animals receiving choleragen rapidly increased to levels approximately ten times greater than those observed in control animals receiving vehicle injections (Fig. 1). Locomotor stimulation was still present 4 d after the injection. In fact some animals still showed significantly elevated locomotor activity 2 weeks after choleragen injection. As the locomotor activity seen in lesioned animals is not significantly different from normal animals receiving choleragen it is probable that the observed effects are postsynaptic.

It is possible to see activation of adenyl cyclase in disrupted membranes from cells previously treated with choleragen[12]. Adenyl cyclase activity was therefore measured in homogenates of NAS of rats previously treated with choleragen (Fig. 2). After 2 h the activity of adenyl cyclase in accumbens homogenates was not significantly different from that in vehicle-treated animals. At 5 h, however, when stimulation of locomotor activity was apparent, adenyl cyclase activity was also elevated. Moreover, at 24, 48 and 96 h after choleragen, when locomotor activity was further stimulated, adenyl cyclase activity was also further increased. Thus the effects of choleragen on locomotor activity and adenyl cyclase activity exhibited similar time courses, showing in each case a characteristic lag period, similar to that observed in other cells after exposure to toxin[12]—for example, stimulation of lipolysis in isolated adipocytes by choleragen shows a lag of approximately 90 min[12]. The locomotor effects after choleragen contrast with those observed after dopamine injection into the nucleus accumbens, when locomotor stimulation is immediately apparent and persists for only about 5 h[8]. As mentioned

Table 1 Adenyl cyclase activity (pmol per mg protein in 2.5 min) in different brain areas of control and toxin-treated rats at different times

	Control			Toxin		
Area	5 h	48 h	96 h	5 h	48 h	96 h

Cortex	128,146	—	162,156	122,162	—	118,202

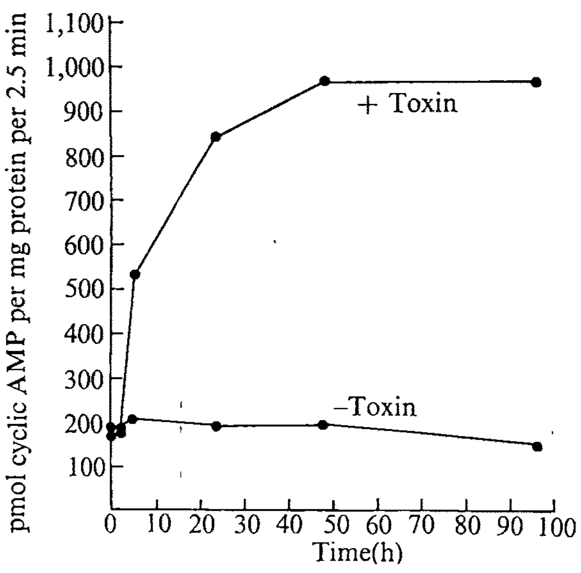
Toxin (1 μg μl^{-1}) or vehicle was injected bilaterally into the nucleus accumbens. Each figure represents one animal (duplicate determinations). Striata, olfactory tubercle and cortex were pooled in each animal. Dissections were carried out according to the methods of Glowinski and Iversen[18] and Horn *et al.*[13]. Adenyl cyclase was assayed as described previously[13].

above, the effects of choleragen in some animals lasted for up to 2 weeks. The duration of the effect may be related to the turnover time of adenyl cyclase molecules in the neuronal membrane Other effects, such as an induction of phosphodiesterase postsynaptically, cannot be ruled out.

We also investigated the effects of added dopamine on adenyl cyclase in nucleus accumbens homogenates from toxin-treated animals (Fig. 3). As previously reported[13], dopamine (10^{-4} M) approximately doubled adenyl cyclase activity when added to nucleus accumbens homogenates from vehicle-treated rats. Two hours after toxin treatment the effect of dopamine did not differ from that in control animals. After 5 h, however, when both locomotor activity and adenyl cyclase activity were stimulated, dopamine was able to increase the adenyl cyclase activity still further. The absolute increase in adenyl cyclase activity produced by 10^{-4} M dopamine 5 h after toxin was significantly greater than the increase produced by 10^{-4} M dopamine after 2 h or in control animals. A similar phenomenon has been reported by Field[14] who found that the addition of noradrenaline stimulated adenyl cyclase both in normal erythrocytes and in cells when adenyl cyclase activity had been increased by previous exposure to choleragen The absolute increase in enzyme activity found with noradrenaline after choleragen treatment was greater than that found in normal cells After 24 h, however, addition of dopamine failed to stimulate adenyl cyclase in nucleus accumbens homogenates above toxin-stimulated levels. Various explanations are possible for this phenomenon. By this time, for example, a maximal stimulation of adenyl cyclase activity in the heterogeneous cell population may mask the increase caused by dopamine. Alternatively dopamine may not further stimulate adenyl cyclase if this enzyme is already maximally activated It is also possible that long term stimulation of postsynaptic dopamine receptive neurones by choleragen leads to a reciprocal desentisation of the postsynaptic dopamine receptors.

To determine how closely the activation of adenyl cyclase in the nucleus accumbens correlated with locomotor stimulation, adenyl cyclase was assayed in other brain regions at various times after choleragen injections (Table 1). Adenyl cyclase activity in homogenates of hypothalamus and cerebral cortex was unchanged at 5 and 96 h; 48 h after injection, however, the olfactory tubercle showed increased activity and at 96 h the striatum did as well. Nevertheless, since locomotor stimulation was seen as early as 4 h after toxin injection it seems likely that activation of adenyl cyclase in the nucleus accumbens correlates best with the behavioural response. Rectal temperature was not increased in toxin-treated rats up to 96 h.

Fig. 2 Effect of choleragen (1 μg in 1 μl) injected bilaterally into the nucleus accumbens on adenyl cyclase activity in homogenates of this brain region at various times after the injection. The nucleus accumbens was dissected out according to the method of Horn *et al.*[13] and adenyl cyclase activity measured as described previously[13]. Points are means of at least three separate incubations of at least four separate nuclei accumbens.



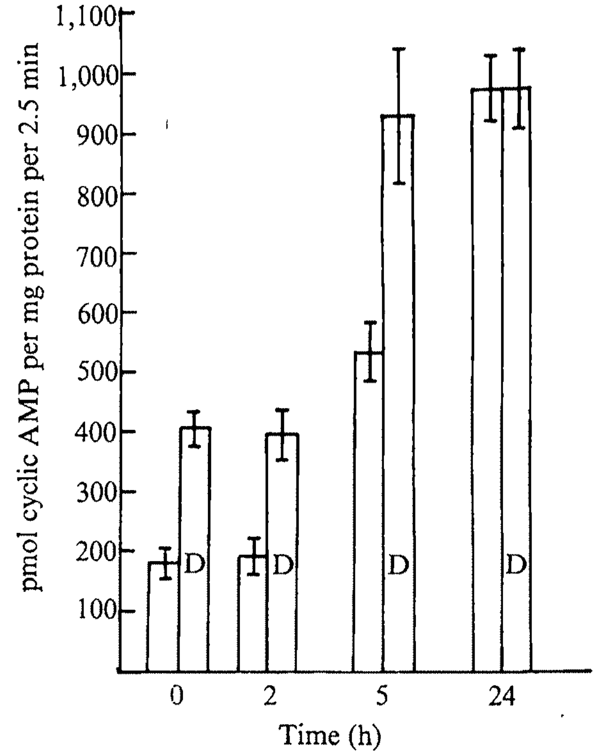


Fig. 3 Effect of dopamine (10^{-4} M) on adenyl cyclase in homogenates of the nucleus accumbens of rats pretreated with bilateral injections of choleragen (1 μg in 1 μl) at various times after the injection Adenyl cyclase assays were carried out as in Fig. 2, except that some assay tubes contained 10^{-4} M dopamine (D). Values represent means ±s.e.m. of at least duplicate incubations of tissue from four or more animals. The increase in adenyl cyclase observed at 5 h with dopamine is significantly greater than that observed at 0 or 2 h. ($P<0.01$.)

It has been postulated that dopaminergic transmission is mediated by cyclic AMP. The present studies demonstrate that a dopamine-mediated behavioural syndrome in rats may be mimicked by activating adenylate cyclase at the same locus, thus bypassing the dopamine receptors. The behavioural effects and the adenyl cyclase activation have the same temporal characteristics. It also seems possible that cholera toxin will be a useful tool for studying other cyclic AMP-mediated phenomena in the CNS.

Domoic and quisqualic acids as potent amino acid excitants of frog and rat spinal neurones

THE finding that kainic acid (Fig. 1*a*) is a potent glutamate-like excitant of rat cerebral[1] and cat spinal[2] neurones has led us to test domoic acid (Fig. 1*b*), which is structurally related to kainic acid and which also occurs in certain marine algae and has similar anthelmintic properties[3,4]. We have also compared the actions of these two compounds with those of α-allo-kainic acid (Fig. 1*c*), a stereo-isomer of kainic acid and a weaker excitant of rat cerebral neurones[1], and with quisqualic acid (Fig. 1*d*), an ascaricidal compound isolated from seeds of the plant genus *Quisqualis*[5]. Quisqualic acid is highly potent as a glutamate agonist at the crayfish neuromuscular junction[6]. Compounds were tested on rat spinal interneurones by microelectrophoresis[7] and on frog spinal motoneurones by superfusion of the procaine-blocked[8] hemisected spinal cord *in vitro*[9]. On both these preparations (see Table 1), the anions of domoic and quisqualic acids were found to be at least two orders of magnitude more potent than L-glutamate, and equal to or stronger than kainate, whereas α-allo-kainate was a considerably weaker excitant.

The high activity of quisqualate extends the range of structures which can replace the terminal carboxymethyl group of L-glutamate with enhancement of activity. These alternative terminal groups include those given in Table 2. All of these acidic terminals contain additional electronegative atoms or groups which may promote an increased interaction of the terminal group as a whole with a corresponding electropositive region of the receptor. The high potency of quisqualic acid (one to two orders higher than that of any of the other compounds of Table 2) indicates an exceptionally effective interaction of the isoxazolidinedione moiety with this electropositive receptor site. The equally potent actions of domoate and kainate may have a similar explanation. Although these two substances have the same carboxymethyl terminal as glutamate, the considerably weaker action of α-allo-kainate, and also of dihydrokainate[2], indicates that the high activity of kainate and domoate is associated with unsaturation in the side chain coupled with a *cis* relationship of the C_3 and C_4 substituents. This suggests the possibility of synergistic action of the side chain unsaturation and the carboxymethyl terminal in the interaction of these parts of the molecule with the electropositive region of the receptor.

When allowance is made for the different experimental conditions used, the high potency of domoate, quisqualate and kainate in depolarising spinal neurones seems to compare with that of certain peptides related to substance P (refs 16 and 17). It is not known, however, whether the amino acids and these peptides act at the same sites. The amino acids are all closely related structurally to L-glutamic acid, and it seems likely that they act on glutamate receptor sites. Whether these are identical with the receptor sites for synaptically-released

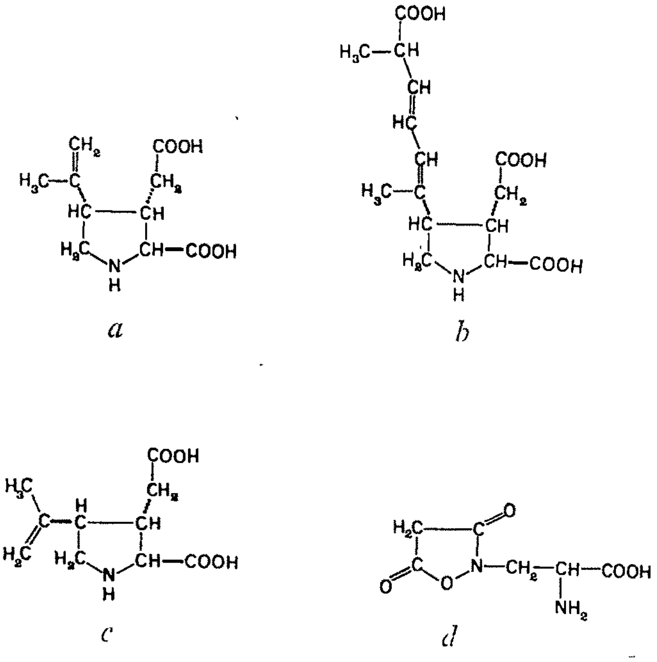

Fig. 1 Structures of kainic acid (*a*), domoic acid (*b*), α-allo-kainic acid (*c*) and quisqualic acid (*d*).

Table 1 Relative potency of amino acid excitants

Compound	Potency relative to L-glutamate = 1.0	
	Rat spinal interneurones*	Frog spinal motoneurones‡
α-allo-Kainate	1–3	0.4 (0.3–0.5; 5)
DL-Homocysteate	3–5	11 (6–14; 10)§
Kainate	40–>200†	127 (85–185; 19)
Quisqualate	25–>200†	389 (151–614; 10)
Domoate	50–>200†	293 (247–373: 10)

For microelectrophoretic administration, domoic, quisqualic and kainic acids were used as the monosodium salts (20 mM) dissolved in 150 mM NaCl, and α-allo-kainic acid as the monosodium salt (200 mM) in water. Monosodium L-glutamate (200 mM in water) and monosodium DL-homocysteate (20 mM in 150 mM NaCl or 200 mM in water) were used as standard excitants. Extracellular recordings of the discharge of rat lumbar spinal interneurones were made using the 4 M NaCl-filled centre barrel of seven-barrel micropipettes. Full details of the preparation have been described[7]. Comparisons of drug potency were made by increasing the current required in each barrel to produce equal frequencies of spike discharge. The superfusion solution used for the frog spinal cord experiments had the following composition: NaCl, 111 mM; KCl, 2 mM; NaH_2PO_4, 1mM; $CaCl_2$, 2 mM; Tris base, 10 mM; $NaHCO_3$, 10 mM; glucose, 12 mM; procaine hydrochloride, 1 mM; and 11.3 M HCl was used to adjust the solution to *p*H 7.9. The temperature was maintained at 13 °C. The effect of a compound added to the solution was measured from the magnitude of the potential recorded between the distal end of ventral roots 8 or 9 and the bathing solution. This potential was generated by changes in motoneurone membrane potential, electrotonically propagated along the ventral root[10]. Procaine was included in the perfusion medium to block conduction in the preparation, thereby preventing the indirect effects of the test substances on motoneurones which could otherwise arise through actions on interneurones. Tetrodotoxin (10^{-7} M) was also used for this purpose in some experiments, and gave identical results. The test substances all caused motoneuronal depolarisation. Dose-response curves were obtained by the addition of the substances to the medium in various concentrations.

*Microelectrophoretic application. Inverse ratios of ejection currents required to achieve equal firing frequencies. Multiple comparisons on eight interneurones in two animals.

†In some instances, merely reducing the retaining currents for the three strongest excitants was sufficient to achieve a firing rate equal to that obtained by 20–60 nA L-glutamate (200 mM) or of DL-homocysteate (20 mM in 150 mM saline). Only minimum potency ratios could be calculated in these cases.

‡Calculated by comparison of ventral root depolarisation caused by various concentrations of excitants with the log dose–response curve for L-glutamate. Comparisons made on three frog cords; range and number of observations in parentheses.

Prolactin-stimulated production of somatomedin by rat liver

GROWTH hormone (GH) and pituitary prolactin (PP) are structurally homologous and have functional similarities both in the lower vertebrates[1] and in mammals[2]. In the whole animal a major function of GH is to stimulate the longitudinal growth of the skeleton, and GH acts by controlling the production of a second series of hormones, the somatomedins. The somatomedins are present in serum and will stimulate the rates of division and matrix production of chondrocytes *in vitro*[3,4]. GH itself has no effect *in vitro* on the cartilage cells, the chondrocytes.

It is now known that GH will stimulate both liver[5] and kidney[6] to produce the somatomedins and that in man the liver is a major site of somatomedin production[7]. If bovine growth hormone (BGH) in a chemically defined medium is perfused through rat liver, somatomedin activity is subsequently found in the perfusate; this somatomedin(s) has properties similar, in many respects, to that found in serum[8–10]. Pharmacological doses of BGH (1–10 μg ml^{-1}) have to be used for significant somatomedin activity to be detected in the perfusates At the concentrations of BGH used, more physiological levels of bovine PP (10–100 ng ml^{-1}) would have been present. We have therefore measured the stimulation of somatomedin activity by PP at concentrations up to 500 ng ml^{-1} in the perfused rat liver system. Our results demonstrate that in this system PP stimulates the production of somatomedin with properties similar to that found following GH perfusion.

Livers from normal male Sprague–Dawley rats (220–260 g) were perfused as described by Dehnel[8]. The liver was perfused first with 100 ml Waymouth's medium[11] supplemented with 0.5% (w/v) bovine serum albumin (Cohn fraction V) to wash out endogenous somatomedin activity, the final 15 ml being collected as a liver control. A further 100 ml Waymouth's medium, containing 0.5% bovine serum albumin, was then circulated three times through the same liver; this medium contained either no added hormones (control perfusion) or BGH (0–10 μg ml^{-1}) or OPP (0–500 ng ml^{-1}). Following perfusion red cells were separated by centrifugation and somatomedin activity assayed by Dehnel's modification of the technique described by McConaghey[5].

Ovine pituitary prolactin (OPP) from both sources at concentrations of 0–500 ng ml^{-1} had no significant effects on costal cartilage metabolism as measured by the rate of $^{35}SO_4$ uptake, an index of cartilage proteoglycan biosynthesis (Table 1). After perfusion through rat liver, media containing either OPP (50 ng ml^{-1}) or BGH (1 μg ml^{-1}) now significantly ($P<0\ 001$) stimulated $^{35}SO_4$ uptake whereas media after control perfusions did not (Table 1). The optimal increase in $^{35}SO_4$ uptake (Table 1) was present after perfusion with either OPP (50 ng ml^{-1}) or BGH (1.0 μg ml^{-1}). All these perfusions were carried out with livers of animals killed at 1100. In contrast perfusion with OPP (50 ng ml^{-1}) of livers of animals killed at 1500 only stimulated $^{35}SO_4$ uptake marginally. Perfusions with BGH clearly stimulated $^{35}SO_4$ uptake at both times (Table 1). Circadian responses to prolactin have been described for other prolactin-stimulated systems[14,15].

Preliminary studies on the properties of the somatomedin activity produced after perfusion of rat liver with OPP demonstrate that they are similar to those we have shown

Table 1 Stimulation of $^{35}\mathrm{SO}_4$ uptake by costal cartilage by media containing PP, or GH, before and after perfusion through rat liver

	Uptake (c.p.m. %) compared with basal media control (hormone added at assay stage)	No. of perfusions	Uptake (c.p.m. %) compared with liver control (hormone added at perfusion stage)
Controls			
Liver control	121±22 (75)	—	100±15 (75)
Waymouth's medium	100± 7(102)	—	82+14(102)
Ovine prolactin			
0 ng ml^{-1}	—	3	113±18 (9)
5 ng ml^{-1}	96± 8 (8)	3	138±28 (9)
50 ng ml^{-1}	99±10 (11)	6	187±15 (15)*
50 ng ml^{-1}(NIH)	106± 7 (7)	6	266±53 (17)*
50 ng ml^{-1}(1500)	—	6	119± 8 (18)†
500 ng ml^{-1}	83± 8 (9)	5	171±14 (15)*
Bovine growth hormone (NIH)			
100 ng ml^{-1}	103±10 (6)	2	77±16 (4)
1 μg ml^{-1}	95±12 (6)	3	181±24 (9)*
10 μg ml^{-1}	121± 6 (5)	2	164±16 (5)*
10 μg ml^{-1} (1500)	—	2	192±27 (6)*

For each assay, costal cartilage sections (3–4 mm long) were taken from each of five Sprague–Dawley rats, each of 50–60 g; the costochondral junctions were discarded. Five cartilage sections, one from each rat, were added to 2.0 ml of the sample to be assayed and the reaction started by the addition of 1.0 μCi ml^{-1} $^{35}\mathrm{SO}_4$ (carrier-free from Radiochemical Centre, Amersham). Each sample was assayed in triplicate. Flasks were maintained at 38 °C for 48 h in a shaking water bath, with an atmosphere of 5% CO_2 in air The reaction was stopped by immersion in boiling water and the uptake of $^{35}\mathrm{SO}_4$ into cartilage proteoglycans estimated by liquid scintillation counting according to the method of McConaghey[5]. Results are expressed as c.p.m. $^{35}\mathrm{SO}_4$ uptake per mg wet weight cartilage compared to the liver control (see text). Each figure is the mean ±s.e. for the number of assays given within the brackets. Unless otherwise stated all perfusions were carried out at 1100, using ovine prolactin (Sigma).

Significance of differences between means assessed by Student's t test: $*P<0.001$; $\dagger P = 0.05$–0 02. The difference between $^{35}\mathrm{SO}_4$ uptake after incubation in medium +50 ng OPP/ml perfused at 1100 and the same medium perfused at 1500 is significant at $P<0.001$.

BGH used was batch B17 from NIH (0.92 IU GH mg^{-1} and <0.50 IU PP mg^{-1}), (ref. 12 and personal communication). OPP preparations were obtained from NIH batch S-10 (26 IU PP mg^{-1} and <0.01 IU GH mg^{-1}) (ref. 12 and personal communication) and from Sigma, batch L-4876 (about 30 IU PP mg^{-1}). Acrylamide gel electrophoresis[13] of these preparations demonstrated that there was less than 5% contamination of the BGH with bovine PP and of the OPP preparations with ovine GH.

after BGH perfusion[8-10]. Thus activity cannot be replaced by the addition of serine and glutamine, which both stimulate cartilage metabolism[16] and which are the only two amino acids present in suboptimal concentrations[9] in Waymouth's medium (Table 2). In addition the OPP-induced somatomedin activity, like that induced by BGH, will stimulate $^{35}\mathrm{SO}_4$ uptake by isolated rabbit chondrocytes in the assay of Ash and Francis[10].

These results demonstrate that both preparations of OPP stimulate somatomedin production by rat liver in the *in vitro* conditions used in the present work. Could these effects of OPP be explained by contamination with ovine GH? The preparations of OPP used contain low levels of GH and are more potent than the BGH used (Table 1). Although we have so far been unable to test ovine GH directly in the liver perfusion system, it is known that ovine GH and BGH have similar potencies in both the weight-gain test in 100 g hypophysectomised rats[12] and the rat-tibial-width test[17]. It is thus most unlikely that the effects of OPP on liver somatomedin production are caused by contamination with ovine GH as the latter would have to be many times more potent than BGH. The distinct actions of BGH and OPP when perfused through the rat liver at different times of the day also provide evidence that each can act separately on liver to stimulate somatomedin production.

Recent clinical evidence has suggested that PP can stimulate *in vivo* both somatomedin production (detectable in serum) and continued skeletal growth in the absence of immunologically detectable GH (refs 18 and 19). These results, together with those presented here, demonstrate that pituitary prolactin can act to stimulate somatomedin production and thus function as a skeletal growth hormone. Further work will be required to elucidate the relative importance of prolactin and growth hormone in the control of mammalian skeletal growth in normal physiological conditions.

Table 2 Properties of somatomedin activity produced following perfusion of rat liver with OPP (NIH)

	No. of perfusions	Uptake (c.p.m %) compared with basal medium
Waymouth's medium	—	100±18(14)
OPP perfusion medium	3	166±21(9)*
Waymouth's medium+serine+glutamine	—	136±13(8)
OPP perfusion medium+serine+glutamine	3	211±24(7)*

Assays were carried out as in Table 1. Serine and glutamine were added where indicated to bring the final concentrations in the assay medium to 1.75 mM l^{-1} and 3.5 mM l^{-1}, respectively[9]. Perfusions were carried out with OPP (NIH; 50 ng ml^{-1}).

$*P$ against controls <0.02.

This work was supported by a grant from the MRC to Professor R. B. Duthie. BGH was a gift from Dr A. E. Wilhelmi (NIH) and OPP from Dr D. Horrobin. We thank Dr L. E. Reichert, Jr for information on the potencies of the NIH hormones.

matters arising

Feeding analogues

THE recent letter[1] on the control of food intake recalls the old caveat that it is very easy to make an analogue; the problem is to know what it is an analogue of.

The analogue presented invokes operation of an on–off feeding switch by the level of 'energy flow'. It is not at all clear what flow of energy is meant. The values used for turn-on and turn-off of feeding roughly correspond with those estimated by Le Magnen and Devos[2] as 'food utilisation', meaning rate of absorption from the gut. The block diagram, however, shows the effective energy flow after the summing point with lipogenesis–lipolysis; that is, for practical purposes, the energy flow triggering the feeding switch of the analogue is total metabolic rate. Now, for rats, the mean increment in metabolic rate from the beginning to the end of a meal (or, with sign change, from the end of one meal to the beginning of the next) is not more than 10%, and is often much less or even negative[2,3]. It does not approach the 230% (18–60 calorie min^{-1}) proposed by Toates and Booth[1]. In the case where the beginning of a meal coincides with the change from rest to activity, and general motor activity continues beyond the end of the meal, then increase in metabolic rate from just before the onset of the meal to its termination can be about 75%, but that change is almost entirely a function of the change from rest to activity with only a small contribution from feeding as such[3].

We therefore seem to have the situation in which energy flow is interpreted as rate of energy absorption from the gut but is inserted into the analogue as if it were metabolic rate; or in which it is interpreted as metabolic rate but gut absorption values are mistakenly used. This is not just a quantitative discrepancy. Even if 'energy flow' denotes metabolic rate and even if realistic values for metabolic rate are used the analogue as presented would have a nonsense output. Since the major changes in metabolic rate are attributable to change between rest and activity and since feeding must be a part of activity[3], feeding by this analogue can only occur during rest, when, by definition, it cannot occur.

The approximate agreement shown between real rats and the analogue for some variables could indicate that these variables are too insensitive for assessment of the function of the model.

[3] Morrison, S. D, *J. Physiol. Lond.*, 197, 305–323 (1968).

TOATES AND BOOTH REPLY—We stated in our second paragraph[1] that the energy flow controlling feeding in our model is that sampled by hypothetical receptors in neural tissue. As the text and figure specify, we make a crude estimate of this by summating the large and considerably variable flow of energy from the gut, with the circadian variations in net flow from or to triglyceride. We are concerned with some of the energy flows between tissues, not the energy flows between the organism and the environment. The dilemma Morrison[2] poses is therefore fallacious. In a later version of the model[3] we allow for circadian variations in heat production by non-receptor tissues; metabolic rate data assist us there, although (as Morrison says[2]) such variations are relatively small. The physiological variables we use are sufficiently sensitive to give unrealistic behavioural predictions when set at values outside the observed range.

We heartily concur with Morrison's point[2] that the empirical interpretation of mathematical models is a treacherous business. We have been able to discuss the relationships between this model and the facts in more detail elsewhere[3]. We welcome this opportunity to counteract misunderstanding that a necessarily brief report almost inevitably permits.

Lead in children's teeth

DAY, HART AND ROBINSON[1] examined the geographical dependence of lead concentrations in urban street dust in several ways. When subdividing data according to city quadrant they noted that the four values ranged from 91 to 122% of the mean value of 970 p.p.m.

We divided our data geographically when studying lead concentrations in crowns of permanent premolar teeth collected from Bristol school dental clinics. The data, plotted according to the home location of the children, fell equally on both sides of a line passing through the centre of the urban area and the Avonmouth industrial complex, approximately 10 km to the north-west. This orientation, however, is approximately at right angles to lead and zinc concentration contours[2] based on extensive sampling of soil and of elm and hawthorn leaves in connection with the regional environmental survey (Sabrina Project).

Table 1 Lead concentrations in tooth crowns according to city zones

Zone	Mean concentrations (p.p.m.)			
	Pb	Zn	Cd	Cu
NE	71±19*	132±32*	4.3	6.6
SW	53±16*	143±36*	4.4	6.6

* Standard deviations (28 samples). Difference (north-east/south-west) significant for Pb ($t = 3.7$, $P<0.001$).

Concentrations of lead in Bristol children's teeth are typically 60 p.p.m. A mean value for tooth samples from 28 children living in a zone to the south-west of the chosen demarcation line was only 75% of that for the same number representing the zone to the north-east (Table 1). There was a non-significant difference in the opposite direction for zinc analyses; the values for cadmium and copper were the same in the two zones.

Another aspect of this type of environmental observation—but in which no geographical distinction was evident—is provided by a study[3] of concentrations of lead and other metals in developing teeth in cases of stillbirth and neonatal death. There was significantly more lead in the dentitions of those born in 1972–73 than in those dating from 1957–63.

Factors influencing effect of hydrocortisone on rat brain tryptophan metabolism

THE concentrations of rat brain 5-hydroxytryptamine (5–HT) and its metabolite 5-hydroxyindole acetic acid (5–HIAA) have been found to be decreased by injection of hydrocortisone[1–3] or other corticosteroids[4]. Benkert and Matussek[5] did not, however, observe changes in 5–HT concentration at various times after injecting hydrocortisone acetate. More recently, Hillier *et al.*[6] reported no change of 5–HT but a rise of 5–HIAA 3 h after hydrocortisone (15 mg kg^{-1} intraperitoneally). The latter authors also found no change in serum total tryptophan and an increase in free serum tryptophan at this time. The following observations may clarify these contradictory findings.

Table 1 Effect of hydrocortisone on tryptophan metabolism in rats

Injected	Plasma tryptophan (μg ml^{-1})		Tissue tryptophan (μg g^{-1})		Brain 5–hydroxyindoles (μg g^{-1} wet weight)	
	Total	Free	Liver	Brain	5–HT	5–HIAA
Saline	27.04±2.05	3.92±0.84	4.89±0.51	2.04±0.19	0.45±0.05	0.87±0.12
Hydrocortisone	22 77±3.38*	1 84±0.51‡	3.66±0.35†	1.45±0.09‡	0.38±0.05	0.51±0.06‡

Male Sprague–Dawley rats (Anglia Laboratory Animals, Alconbury) 35 d old were used. Animals were killed 6 h after injection. Plasma tryptophan was measured as described previously[10], tissue tryptophan by the method of Denckla and Dewey[11] and brain 5–HT and 5–HIAA by the method of Curzon and Green[12]. Results expressed as mean ± s.d. of six observations. Different from saline injected controls.
* $P<0.05$.
† $P<0.01$.
‡ $P<0.001$.

Table 2 Influence of age on effect of hydrocortisone on kynurenine production by isolated perfused rat liver

Age (d)	Injected	Hepatic kynurenine production (μg^{-1}g^{-1}h^{-1})
35	Saline	35±5(4)
	Hydrocortisone	139±32(4)*
100	Saline	22±8(4)†
	Hydrocortisone	65±31(5)*‡

Livers were perfused by the method of Hems *et al.*[13] with a semi-synthetic medium[14] containing tryptophan (1.0 mM). Rats were injected with hydrocortisone (5 mg kg^{-1}) or saline 3 h before the start of the liver perfusion. Results expressed as mean ±1 s.d. with number of observations in brackets.
* Different from saline-injected control rats of same age $P<0.01$.
† Different from saline-injected 35-d rats $P<0.05$.
‡ Different from hydrocortisone-injected 35 d rats $P<0.01$.

- Using the hydrocortisone dose of Hillier *et al.*[6] of 15 mg kg^{-1}, we confirm that there is no change in total plasma tryptophan 3 h after injection of the steroid, but also found no alteration in free tryptophan. In the original work however[1,2] 5 mg kg^{-1} hydrocortisone (as the sodium succinate derivative) was injected intraperitoneally and brain 5–HT and 5–HIAA determinations were made 6 h later, at which time the decrease in both compounds was maximal. Using this protocol we now find a fall of both total and free plasma tryptophan and a fall of tryptophan concentration in both liver and brain (Table 1). Brain 5–HT decreased but not significantly, while 5–HIAA was considerably and significantly lowered (Table 1).
- Brain tryptophan, 5–HT and 5–HIAA are all unaltered following hydrocortisone (5 mg kg^{-1}) administration to gerbils[7]. In these animals (unlike the rat) the hepatic enzyme, tryptophan pyrrolase is not induced by hydrocortisone[7,8]. This is consistent with an association between the increased hepatic pyrrolase activity in rats following hydrocortisone[2] and the changes in tryptophan metabolism now reported.
- Other factors may also be important when studying the effects of hydrocortisone on tryptophan metabolism. The time courses of hydrocortisone actions depend on the form in which it is injected. Hydrocortisone sodium succinate leads to more rapid changes of pyrrolase activity than the less water soluble hydrocortisone acetate or free steroid[9].
- The age of the animals is also important. Older animals (100 days or more) do not exhibit the brain 5-hydroxyindole changes or the large hepatic pyrrolase induction shown by younger rats (35 days; 120 g) following the same hydrocortisone dose per kg body weight[9]. This smaller increase of pyrrolase activity in older animals was previously demonstrated by measuring enzyme activity in liver homogenates after hydrocortisone treatment, and has now been demonstrated in the perfused liver. Thus, kynurenine production from tryptophan by isolated perfused rat liver preparations is much lower in older animals both before and after hydrocortisone (5 mg kg^{-1}) pretreatment 3 h previously (Table 2).

Thus we have shown that hydrocortisone can alter tryptophan metabolism both peripherally and in the brain and confirm that changes are consistent with decreased brain 5–HT synthesis. These changes are, however, dependent on several factors; times of observation, age of animals and the hydrocortisone preparation used. Though it would be rash to extrapolate too readily from acute pharmacological experiments to a chronic illness such as endogenous depression, the possibility exists that similar changes have significant roles in the aetiology of psychiatric disorders in some subjects[1,2] or, indeed, in the 5–HT metabolism of normal subjects in certain circumstances.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Narrow-angle cosmic-ray anisotropies

SPELLER, *et al.*[1] have presented a measurement of the diurnal cosmic-ray anisotropy, as found with underground muons in London. An additional, but quite different, interpretation of their data is, however, possible.

From the widely accepted diffusion models for cosmic-ray propagation in the Galaxy, one could expect only a diurnal anisotropy (24-h wave). A newer model[2], based on adiabatic propagation of cosmic rays, predicts that an excess could occur within some small region of the celestial sphere. The direction of the excess would depend on the orientation (in space and time) of the source object relative to galactic magnetic field lines which connect the source with the Solar System.

A narrow-angle anisotropy near the celestial equator was reported[3] and confirmed[4] during the time of the London experiment (see Table 1). It resembled an earlier anisotropy[5] in that it was observed at the time of a sunspot minimum, then gradually faded away. The London data are shown in Fig. 1, split into periods before, during and after the 1964 anisotropy. The point at 18 h is $3.2\sigma_N$ (standard deviations) above the curve.

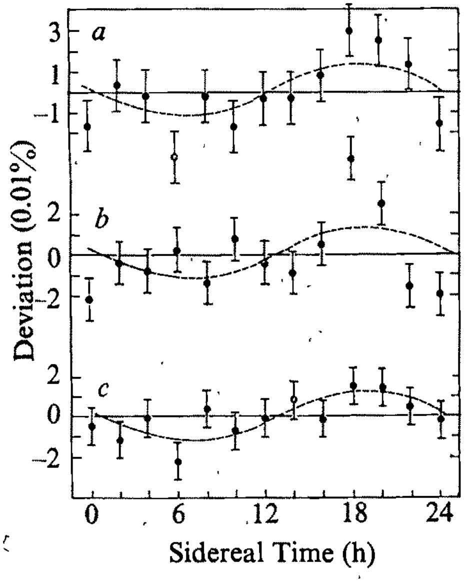

Fig. 1 The London data for: *a*, 1961–62; *b*, July 1963–June 1964; *c*, 1965–68, showing the deviation from the average intensity against sidereal time. The sine curve fit to the total data is shown. The anisotropy is present in *b*, but lacking in *a* and *c*, in agreement with ref. 3.

The apparent position of this peak agrees with the Winnipeg data[3] if one includes geomagnetic deflections calculated for particles of 100–200 GeV. (This explanation is inadequate for the reported Hong Kong position[4]. Other factors, such as accessibility to lower declinations, may have played a role.) This estimated energy is above the thresholds of the Winnepeg and Hong Kong detectors but is near the London threshold at a zenith angle of 51° (the efficiency is about 10% at 160 GeV and 90% at 1600 GeV). The small size of the anisotropy in the London data (0.03%, by comparison with 0.3% at Hong Kong and 10% at Winnipeg) can be understood in terms of the energy threshold, the large zenith angle and the wide angular aperture.

Table 1 Narrow-angle anisotropies

Experiment location	Nagoya	Winnipeg	Hong Kong	London
Latitude (°N)	35	50	22	51
Period observed	1952–56	Dec. 1963–Sept. 1964	Jan. 1964–Mar. 1964	1963–64
Not observed	1957–61	Nov. 1964–Dec. 1964	—	1965–68
Declination (°N)	0.5	0±18	—	—
Right ascension (h)	5.25	20.5*	23*	19*
Angular aperture (°)	5×7	±18	±45	±63
Particle rigidity (GV)	280±40	>40	>30	150±50
Significance (standard deviations exceeded)	6	16	5	5

*Uncorrected for geomagnetic deflection.

The uncertainties σ_N shown in Fig. 1 arise from counting statistics only. The London authors argue for the use of $1.4\sigma_N$, but the scatter of their data around their sine curve in Figs 1*a* and *c* is $\sigma_S/\sigma_N = 0.89$ and 0.84, whereas the expected scatter is $\sigma_S/\sigma_N = 0.93 \pm 0.20$. If one removes the two points at 18 h and 20 h, the other points fit well to a straight line. The two points are $5.0\sigma_N$ and $2.9\sigma_N$ above this line.

During previous sunspot minima, conditions have apparently become favourable enough to observe two narrow-angle anisotropies of rather low energy. Each would be caused by a cosmic-ray source near our magnetic field line in the Galaxy. The next sunspot minimum is expected early in 1976 (ref. 6).

I thank H. E. Bergeson for discussions and the London authors for correspondence and data. This research has been supported by NASA.

[6] Waldmeier, M., *Nature*, 253, 419 (1975).

ELLIOT AND THAMBYAHPILLAI REPLY—We are sceptical about Barrowes's interpretation of our (London) data because: (1) We disagree with the use of $\sigma_N = 100/\sqrt{N}$ % in assessing the statistical reality of the deviation from the mean at 18 h. Our own analysis of the scatter of harmonic coefficients shows that a value of $\sigma_N = 1.8\times(100/\sqrt{N})$ % is more appropriate than the lower limit used by Barrowes.

(2) The energy thresholds given in his Table 1 do not in themselves provide a satisfactory basis for comparing the magnitude of the effect to be expected at the various stations. To do this, it is necessary to use the complete response functions for the detectors concerned.

(3) We cannot see how a narrow-angle anisotropy can be observed at the Earth for primary cosmic rays with $E \leqslant 200$ GeV because of the wide spread in the deviation of such particles in the interplanetary magnetic field. The angles through which these particles would have been deflected by the field at any time during the recent solar cycle is much greater than that in the geomagnetic field.

Messenger RNA abundance and gene regulation in eukaryotes

BISHOP *et al.*[1] found three abundance classes for poly(A)-containing mRNA in HeLa cells (17 sequences of about 8,000 copies per cell, 350 of about 440 copies and 35,000 sequences of about 8 copies). This situation may be quite general. Green, Goldberg and Todaro[2] found three ranges of relative collagen synthesis rates (1.5–14%; 0.15–0.4% and beyond 0.002%) and even where only one or two abundance classes are found, non-poly(A)-containing mRNA may contain another abundance class[3].

A rather simple control system for gene regulation, similar to one previously proposed[4,5], may explain this rather reduced number of mRNA abundance classes which should correspond to three possible degrees of gene activation. Histones usually block DNA transcription, but specific activators (probably non-histone nuclear proteins) controlled by some interrelated gene triggers, may open different DNA portions to transcription by combining with "promoter" regions. This would be the first control level. Within the unblocked DNA portions a second control level could act, based on less stringent repressors (of the type found in bacteria) also controlled by triggers of interrelated genes. High abundance mRNA should correspond to unblocked–derepressed structural genes, medium abundance mRNA to unblocked–repressed structural genes. The many very low abundance mRNA sequences may correspond to accidental transcription of blocked structural genes during DNA replication, which may also be required for unblocking DNA portions in cell differentiation ("quantal mitosis"[6]). Alternatively, "switching on" of histone acetylation and phosphorylation may produce a general weakening of the histone block on transcription, allowing the appearance of the very low abundance mRNA class.

Structure of graphite

ERGUN[1] has suggested a structure for graphite based on new X-ray diffraction data, in which two of the carbon–carbon bonds lengths in the six-membered ring of any layer are shorter than the other four. This gives rise to the so-called 1,4 quinoid structure. The atomic positions in this structure are

$$(0,0,0), (x,\bar{x},0), (\tfrac{1}{2}+\tfrac{x}{2}, \tfrac{1}{2}-\tfrac{x}{2}, \tfrac{1}{2}),$$
$$(\tfrac{1}{2}-\tfrac{x}{2}, \tfrac{1}{2}+\tfrac{x}{2}, \tfrac{1}{2})$$

with $x = 0.318$. The resulting square of the geometric structure factor is then[1]:

$$F^2 = 16\cos^2 \pi x(h-k)\cos^2(\pi/2)\times$$
$$\times\ [(1-x)(h-k)+l]$$

(If the value of x is $\frac{1}{3}$, then the commonly accepted graphite structure results. That structure comprises regular hexagonal nets, stacked in the sequence . . .[AB] . . .) Ergun used his measured values of the four observed ($h\ h\ 0$) reflections (the F^2 values of which, according to the equation shown here, are independent of the parameter x) to obtain a function that he did not publish but which he used to reduce the other seven observed ($h\ k\ 0$) intensities to an F^2 basis. The value for x of 0.318, which was apparently obtained by trial and error, was then used to calculate values for the remaining seven $F^2{}_{hk0}$ values. The agreement between $F^2{}_{\mathrm{obs}}$ and $F^2{}_{\mathrm{calc}}$ is astonishingly good, with

$$R_2 = 100x\Sigma|F^2{}_{\mathrm{obs}}-F^2{}_{\mathrm{calc}}|/\Sigma F^2{}_{\mathrm{obs}}$$
$$= 1.25\%$$

Ergun stated that "it was evident [on the basis of his observation of sharp diffraction maxima] that the lattice is hexagonal", by which he meant $a = b$ with an angle of 120° between them. The symmetry of his structure is, however, not hexagonal, but orthorhombic. Thus, not all reflections having identical spacings have the same calculated values of F^2. In particular, reflections having the same value of (h^2+hk+k^2) will occur at identical scattering angles, but not all of these are symmetrically equivalent.

For example, the reflection (210), with $F^2{}_{\mathrm{calc}} = 1.075$, $F^2{}_{\mathrm{obs}} = 1.08$ (Ergun's figures) occurs at the same diffraction angle as $(3\bar{2}0)$ and $(3\bar{1}0)$, and the calculated F^2 values of these two reflections, as given by the equation already shown, are 0.449 and 1.184. The average relative value of $F^2{}_{\mathrm{calc}}$ is thus 0.903. The adjacent reflection, (200), with $F^2{}_{\mathrm{obs}}= 0.80$, is, in Ergun's table, in excellent agreement with $F^2{}_{\mathrm{calc}}= 0.804$. This reflection is actually, however, the weighted average of (200) and $(2\bar{2}0)$, and the latter, with $F^2{}_{\mathrm{calc}}=1.184$ leads to a relative $F^2{}_{\mathrm{calc}}$ of 0.931. The calculated F^2 ratio for (200)/(210) is thus 1.031 instead of the 0.748 given by Ergun, and is no longer in almost exact agreement with the observed ratio of 0.741.

Because Ergun did not report his raw intensity data, but only those "corrected" with an unknown function it is not possible to use them to come to any further conclusions regarding the structure of graphite. But in any case it is clear that no support for the quinoid structure is provided by the spectacular agreement between the values of $F^2{}_{\mathrm{calc}}$ and the $F^2{}_{\mathrm{obs}}$, which now becomes merely interesting.

Environmental modification of a genetically based behaviour pattern in *D. melanogaster*

THRELKELD *et al.*[1] have shown that the reduced mating success of mutant yellow males with normal females of *Drosophila melanogaster*[2] can be alleviated by genetic selection. It is important to realise that genetically based differences in behaviour are not rigid but are contingent on the environment in which they are measured.

In the present study to determine the environmental modifications necessary to increase the mating success of yellow males, two inbred strains of *D. melanogaster* were used, one wild type and the other yellow. All matings were conducted at 25 °C under continuous light and were always between virgin 1–2-d-old wild-type females and yellow males. Each pair of flies was anaesthetised with ether, placed in a vial (23 × 85 mm) containing 10 ml of yeasted propionic acid medium and left for 9 d. A mating was scored as successful if progeny were present at the end of this time.

Table 1 Percentage mating success

Sex ratio	Sample size	Matıng success
1:1	249	0.8
1:2	64	1.6
1:3	37	21.6
1:4	78	21.8
1:5	53	9.4

The sex ratio was varied from 1 : 1 to 1 : 5 (female : male). The results (Table 1) reveal significant differences between the 1 : 1 ratio and both the 1 : 3 ($P<0.001$) and the 1 : 4 ($P<0.001$) ratios. These remain significant even if mating successes are compared on a per male basis. It would seem that mating success is not a simple linear function of the number of males present and that a highly favourable interaction effect occurs when the ratio of males to females is three or four to one.

Artificial selection for seven generations was able to increase the competitive mating success of yellow males from 36% to 67% (ref 1). A change in sex ratio can increase non-competitive mating success from less than 1% to 22%. Environmental modification can produce significant changes in genetically based behaviour patterns.

This work was supported by a Scholarship from the National Research Council of Canada.

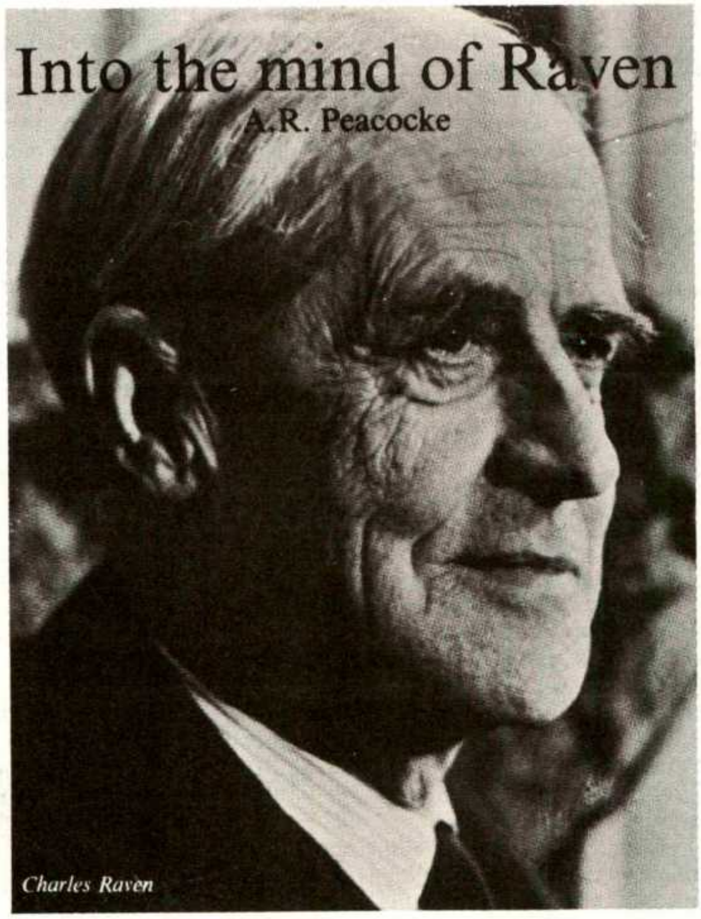
Into the mind of Raven

A.R. Peacocke

THE biography* of a leading theologian would not ordinarily find reviewing space in the columns of *Nature*. But there was nothing ordinary about Charles Raven either as a theologian or as a man. What other Regius Professor of Divinity at Cambridge (or anywhere else) has, while in office exercising his normal academic duties, produced a monumental biography of a man of science? The man of science was, of course, John Ray, the first and perhaps the greatest, British naturalist, who produced the first accounts of county flora in 1660 and a comprehensive *History of Plants*. If for nothing else, we owe Charles Raven's own biographer, Dr F. W. Dillistone, an immense debt for reminding us of the devoted and meticulous research with which Raven brought his task to its accomplishment when he published *John Ray: Naturalist* in 1942. Raven, so Dillistone tells us, collated every record of Ray's travels and research, translated countless descriptions and identifications from Latin and Greek, and collected nearly all the plants, birds and insects that Ray records—often from the same localities.



Charles Raven

The resulting classic biography was itself the work of a unique man and Dr Dillistone's immensely readable, sensitive and thoughtful account of Dr Raven's life and work takes the veil off Raven's mind, taking us as far as we are ever likely to be able to penetrate into that vast treasure house. Dillistone shows us how Raven's bond of sympathy with Ray lay in their both sharing a vision of the unity of scientific and religious experience, that vision partly expressed in the title of Ray's widely influential *The Wisdom of God in the Works of Creation* (1691).

Raven was a born naturalist—observant, sharp-eyed, patient (able to wait for long hours in atrocious weather for his observations)—a beautiful illustrator and draughtsman (learnt from his mother), an accomplished Latinist (undaunted, indeed revelling in, the Linnean scheme) and an avid collector, with an accurate and comprehensive memory. Dillistone shows how the zest for living creatures never left Raven and how his joy and thrill in the careful observation of nature was fundamental to his total vision. He takes us through Raven's formative years at home and at the University of Cambridge and makes it clear to those of us who knew Raven only at a distance how it was that a student of first the classics and then divinity could have had such a zest for and sympathy with the natural sciences. Apparently this zest and sympathy originated from his mother's training, so that perhaps we are less surprised when Dillistone tells that while working for the Divinity Tripos, Raven attended the Lectures of William Bateson, who was one of the outstanding exponents, with a deterministic emphasis, of the new genetics during the early years of this century. This, so Dillistone judges, and those of us who remember Raven recalling his experience of Bateson's lectures will agree, was one of the chief goads to Raven's intellectual quest through his life—the interpretation of evolution as a non-deterministic and creative process which is the clue to the natural emergence of the human person. The consummation of this process Raven saw in a transmutation of human personality by the illumination and extension of human existence, which the Christian faith provided through its focus on the man in history in whom it was first achieved and who thereby opened the way for others.

By enriching this biography with a careful assessment of the context of thought within which Raven moved at various stages of his life, Dr Dillistone has provided us not only with an account of an exceptionally gifted man, but also with a chronicle and diagnosis of the ebb and flow of that Christian liberalism of which Raven, along with William Temple, was one of the most brilliant exponents. For this reason, this biography comes at an especially opportune time, when the near-collapse of radical politicised versions of Christianity, at least among students in this country, has left the enquiring with apparently only one other alternative—that of a conservative biblicism which Raven regarded as an affront to the intellectual integrity of any critically enquiring youthful mind ready to apply the same standards of judgment to its religion as to other intellectual enquiries, including that of science.

With Raven lecturing, writing and preaching in Cambridge, a critical, enquiring, explorating, yet at the same time, integrating and visionary Christian outlook was clearly available as an alternative to such conservatism, and Dillistone reminds us how science and mathematics students responded to it; men whose subsequent careers were

---

**Charles Raven: Naturalist, Historian, Theologian.* By F. W. Dillistone. Pp. 438+18 photographs. (Hodder and Stoughton: London, 1975.) £5.25.

as different as those of Charles Coulson (the theoretical chemist who became Rouse Ball Professor of Applied Mathematics at Oxford) and Ian Ramsey (who became Nolloth Professor of the Philosophy of Religion at Oxford and later Bishop of Durham). Dr Dillistone's biography is opportune because the conservative, intellectually uncritical kind of Christianity from which Raven released so many, is today attractive in its simplistic unambiguity to many of the young who can scarcely hear any other voice. "Raven, thou shouldst be living at this hour", but, failing that, we can again catch those rich and profound cadences through his faithful biographer.

But Dr Dillistone is no adulatory sycophant. He shows us where this idol had feet of clay: his failure to understand the crises of continental thought under the impact of the Nazis; his over-magisterial non-suffering impatience with 'fools'; his too-rapid dismissal of any dialectical, non-unified system of thought; his almost pathological concern with his supposed rejection by "the Establishment" of his day on account (he supposed) of his unpopular pacifist views and of his support for the ordination of women.

More positively, Dr Dillistone has dug deeply to discover accounts of Raven's moments of illumination which carried him through the devastating experiences at the Front in the first World War and through tragic bereavements at critical moments in his life. The inner life of the Regius Professor, the Master of a Cambridge college and the Vice-Chancellor of that university, are gently, surely and shrewdly unveiled for us in a way which shows how what Raven loved to call "the sublime law of sacrifice" (quoting Fabre) lay behind the public image.

Those of us who have known Raven through his writings can, with the help of Dr Dillistone, now meet him as the complex, exceptionally gifted and contradictory man he was. Even more important, those who have known neither him or his writings can, through this sympathetic biography, now be inducted into the thought of a man who combined enthusiasm for science with insight into religious experience into a unique amalgam so clearly needed by our disrupted and fissiparous culture. For Raven, in both spheres, the exploration was liberal and open-ended and productive of that unity of vision shared, across the centuries, with Ray.

Not whole but just some of the parts

Microbial Communities in a Forest-Rendzina Ecosystem: The Pattern of Microbial Communities. By I. M. Szabo. Pp. 415. (Akademiai Kiado; Budapest, 1974.) £10.50.

THE microbial ecology of soil is a subject which has in the last few years acquired a voluminous literature at an ever increasing rate. Unfortunately, this has been achieved without any comparable increase in the understanding of the systems under study. The diversity of microbial communities, their functions and their microhabitats have obscured all attempts to derive any but the most basic ecological generalisations. Professor Szabo attributes this failure, in part, to a dispersal and dilution of research effort. In spite of the complex nature of the system (or perhaps because of it) research planning has tended to concentrate on specific functions, organism groups, or ecological parameters. This has resulted in a science in which there is considerable knowledge of some of the parts but little understanding of the whole.

The philosophy of the studies reported in this volume is different. For over 15 years Professor Szabo and his colleagues have conducted an intensive study of soil microflora and fauna in a single area of oak-hornbeam forest in western Hungary. The concentration on a single site is deliberate. Only in that way can "those general principles which govern the activities of complex saprophytic communities in the soil" be recognised and understood. It is in that context that the reader is asked to judge the contents of this book.

The first chapter describes features of the forest site at the ecosystem level; in Chapter Two the focus becomes finer and we are given accounts of micromorphological studies, the utilisation of techniques of soil sectioning and electron microscopy, and the distribution of microbial communities and their microhabitats. The third chapter gives an account of the distribution of soil animals and microorganisms in relation to the conditions of moisture and temperature in the soil.

It is not until Chapter Four, however, that the main subject of this book is encountered: the structure and species composition of the microbial communities occupying selected habitats of the forest-rendzina soil. A discussion of the current status of the species-concept in the Actinomycetes leads on to a consideration of the techniques of multiple character testing and numerical similarity analysis by which Professor Szabo defines the members of his microflora. In this chapter 34 species-groups from the A horizon of the soil are described using those methods; the description is supported by many pages of tabulation of characteristics and by a discussion of the validity of the status of the species groups in comparison with the conclusions of other workers. In the succeeding two chapters this process is repeated for the actinomycete and bacterial floras of other habitats, notably the gut and faecal communities of the larvae of *Bibio marci*, an important component of the fauna active in soil decomposition, and the rhizoplane community of *Robinia pseudo-acacia*. These three chapters comprise two thirds of the total text; they are almost wholly devoted to the reporting and discussion of the taxonomic studies. This gives a highly specialised character to the book that seems out of keeping with the drift of the early chapters and the stated aim.

The interest of the same readers may, however, be reclaimed by the contents of the last chapter. Here, there is an enormously stimulating discussion ranging over many aspects of the structure and functioning of the microbial communities of soil, including such topics as microbial successions, the role of microbes in soil humification and fertility, the dissemination of soil microbes, and the maintenance of the genetic diversity of soil populations. Here also the ecological implications of the work described in the three main chapters is allowed to struggle free of its taxonomic clothing and to be seen in a wider ecological context.

I was left with a strange impression that I had read two books in one. Anyone with an interest in the microbial ecology of the soil who can gain access to the book will find much to stimulate him in the early chapters and in Chapter Seven. Whether they will find it worth paying the expensive price for the sake of the specialised remainder will depend on their own particular interests. A number of reservations must also be recorded. I found it difficult to be convinced by much of the experimental work in Chapter Three; for instance the relevance of survival testing of microbes over the temperature range 35–65 °C is obscure when related to their activity in a forest soil of temperate climate—particularly when no suggestion is made of potential thermophilic phases. The lack of detail in the reports of the quantitative ecological data contrasts strongly with the admirably complete treatment of the taxonomic data and detracts from the impact of the topics discussed in Chapter Seven.

Nevertheless, this well-produced book remains an important contribution to the literature, partly to the specialised field it serves but more generally because of the opportunity it affords for an appraisal of the Szabo philosophy of "intensive, single-site study".

Mike Swift

Spectroscopy . . .

Laser Spectroscopy. By Richard G. Brewer and Aram Mooradian. Pp. xi+671. (Plenum: New York and London, 1974.) $41.40.

THIS volume contains the proceedings of a Conference held at Vail, Colorado, between June 25 and 29, 1973—one of the most interesting conferences I have had the privilege of attending. The book reports on 45 invited papers and reflects a significant landmark in the application of lasers to fundamental physical investigation in that the impact of tunable laser sources, or related methods, on the spectroscopy of atomic and molecular systems could be seen clearly for the first time. Orders of magnitude advances in resolution and/or spectral brightness were demonstrated and used. The meeting, which was international and interdisciplinary, covered a spectrum from the ultraviolet to the far infrared and microwave regions; it was set in context by addresses covering wider fields of physics by Gerhard Herzberg and Edward Teller.

In some ways visible wavelength, dye lasers are the most highly developed: examples of high resolution (50 kHz) atomic beam spectroscopy, spectroscopy of selectively excited atomic states, saturated spectroscopy eliminating Doppler broadening, and quantum beats—modulations arising from the coherent superposition of excited states observed in fluorescence—are variously reported from Cologne, Columbia, London and Stanford universities.

Spectroscopy using tunable infrared lasers is attendant upon the continuing development of the different laser systems. Parametric oscillators ($LiNbO_3$, CdSe) now cover the range from 0.6 μm to 11 μm (but not continuously) and, with mixing techniques, reach 18 μm. As reported by Stanford University, however, resolution is so far disappointing—linewidths are only 0.1–1 cm^{-1}—and good spectra are as yet rare. Four-wave parametric mixing in alkali metal vapours, developed by the International Business Machine company, now covers the range 2–25 μm with rather similar properties.

By contrast, semiconductor diode lasers, until now originating mainly from the Lincoln Laboratory, MIT, collectively extend from 1–32 μm and have yielded many high quality spectra though, individually, they cover only a few wavenumbers. These lasers can now be operated with external cavities. Hyperfine splitting, Λ-doubling and Zeeman splitting effects using laser linewidths sometimes as low as 100 kHz are demonstrated. Progress on Spin-flip Raman lasers is reported from MIT, Bell Laboratories and Heriot-Watt University; this technique retains advantages in its combination of high power and narrow linewidth (from 1 kW at 0.02 cm^{-1}, pulsed, to 1 W at 100 kHz, continuous wave) and is now giving high quality spectra.

Numerous experiments using lasers on molecules and atoms are reported, all reflecting the high precision of measurement now possible. Subjects covered include Lamb-dip spectroscopy, infrared microwave double resonance, precision calibration and stabilisation, heterodyning, laser photochemistry and astrophysical distance measurements. This excellent book is essential for any laboratory concerned with laser spectroscopy.

Upright or low bindweed, *Convolvulus spithamaeus.* From *Wild Flowers.* Revised edition. By Homer D. House. Pp. 362+364 colour plates. (Collier–Macmillan; New York, May 1975.) £5.00.

. . . and spectroscopy

^{13}C NMR Spectroscopy: Methods and Applications. By E. Breitmaier and W. Voelter. Pp. xiii+303. (Chemie: Weinheim, 1974.) DM98.00.

THIS book by these authors has obviously grown to adult status from their earlier review in *Angewandte Chemie.* Their child has expanded naturally in each of its parts and has matured considerably but, genes being what they are, is still bound by the same limited outlook, which is strictly organic. Its name, therefore, could be very misleading to the prospective buyer, especially if he detects the strong physical accents of the companion monographs in the family series. Evidently the godfather realised the child's predilections, since his foreword uses the term 'organic' in every other line, but it is clear that the editor ought to have exerted his influence and judgement at the baptism.

The first three chapters give 20 pages of basic, introductory discussion of nuclear magnetic resonance (NMR), 45 pages on methods, and another 45 on the relationships of structure to NMR data, mainly covering shifts (20 pages) and coupling constants (20 pages) with only 6 pages on relaxation times. The introductory first chapter is rather unbalanced—there is much detail, unused later, concerning the Bloch equations, and arguably not enough on complexities in spectra. It contains annoying, but perhaps trivial, mistakes or views; for example, it is stated that shifts, unlike couplings, are not true structural parameters, and there is a misleading labelling of the spin levels in an AX system. A short discussion of relaxation effects in that system would have been useful. Chapter 2 is good but could have been improved by the inclusion of a section on assignment techniques, if only in summary or even tabular form. In chapter 3 the authors acknowledge that their adopted sign convention for shifts is unusual but they give no reason for so sprinkling their handsome volume with a plethora of expensive negative signs.

The second half of the volume is devoted to applications. There are only two chapters, rather arbitrarily divided into "Organic Compounds" and "Natural Products". The volume contains virtually nothing on carbon-containing ligands in either organometallic or other complexes. Discussions of paramagnetic systems and of the phenomenon of chemically induced polarisation are avoided. The latter, even if it had not been extensively applied to ^{13}C studies at the time of writing the book, was clearly going to prove important even then.

The authors have done reasonably well in avoiding the dangers arising from early abstraction of material and slow book production in a developing field but, inevitably perhaps, occasionally important assumptions are not sufficiently emphasised or even explicitly stated—for example the extreme narrowing condition in the Overhauser section, and the symmetry or motional conditions in the lanthamide shift section.

In spite of these criticisms and the high price, the book has attractions. It is very well produced, pleasingly designed, printed and presented, and has 82 excellent figures.

I should like to congratulate the authors on their clarity of expression, especially as they have written in a language which is not their own.

Young men

Essays on the Nervous System. By R. Bellairs and E. G. Gray. Pp. viii+511. (Clarendon : Oxford; Oxford University Press : London, 1974.) £11.50.

THIS admirable book consists of nearly 20 essays by former pupils and colleagues of J. Z. Young—essays well chosen and substantial. They cover most of Young's fields of interest—endocrine activity in the nervous system, by the late Sir Francis Knowles; learning in the octopus, by M. J. Wells; synaptology, by E. G. Gray; the vertebrate retina, by B. B. Boycott—as well as the hard core of the organisation of the central nervous system represented by Zeki on the visual cortex, Webster on vision in the pigeon, Nadel and O'Keefe on the hippocampus, and Ralston on the spinal cord. The peripheral nervous system includes the muscle spindle described by David Barker—a pupil of Young at Oxford before his University College days—growth of nerve fibres in tissue culture by D. W. James; and Hall-Craggs on mammalian skeletal muscle. P. K. Thomas on nerve injury reminds us of Young's war time interests from which grew new lines of immense importance.

It is an enormous range of interests, in which he has touched little without making it flower. Sometimes the flowers take unexpected shapes. In Zeki's work sharp and detailed localisation appears as the ground plan of the various visual re-representations in the prestriate cortex. In the paper on the hippocampus a new and fascinating model is put forward to account for the detailed and regular structure of that puzzling formation.

This is, in fact, the thread that joins up this variety of contributions—the need for detailed and exact knowledge of structure on which to base any account of function in the nervous system. There was a time when random spread and connection of nerve fibres was believed to occur even in the visual cortex. Since then we have learned of the precise limits of eye dominance and orientation columns in the cortex, the sharply defined decussation of fibre tracts in the octopus, and the orderly growth and regrowth of fibres in the optic tracts and tectum. It is arguable that although there have been great advances in knowledge of synaptology from electron microscopic studies of the retina described here by Boycott and more generally by Colonnier, we still need more information at the optical microscopic level. Golgi stains give us a small sample of the cells present but only as individuals isolated from each other. Perhaps what we need more is something which does not yet exist—Golgi-like pictures limited to small groups of cells which are immediately linked to one another, instead of being picked out by the vagaries of staining.

This thread runs through Graziadei's account of the curious regeneration to be found in olfactory nerves, in Guillery's account of experimental production of structural changes in visual pathways, and in Webster's valuable account of the present state of knowledge of visual pathways in birds. Rather oddly, it is not obvious in Wall's essay on cognition and perception as a preliminary to relevant behaviour. What better title could one have for Well's account of the octopus than 'A location for learning'?

This book is a worthy tribute to the work and inspiration of one who has moulded twentieth century studies of the nervous system. **D. Whitteridge**

Applied estimation

Applied Optimal Estimation. Edited by A. Gelb. Pp. 374. (MIT Press : Cambridge, Massachusetts and London; 1974.) $6.95.

THE title of this eclectic compendium is a conventional solecism. 'Applied' means applicable as in 'applied mathematics'. Examples of the use of optimal estimation are included to elucidate the techniques rather than to discuss the application.

A high proportion of computer time in current use is expended on optimally fitting data to models which are ill founded in theory and erroneous in application. Examples abound in every field, from particle physics to town-planning. A mathematically written textbook which sets out conditions under which models can be built up is needed; it may have the same title as this book but this book is not it. The fact that this volume will increase the number of persons technically equipped to estimate model parameters optimally may well turn out to be a misfortune.

But in spite of reservations about what this book is not, it is an excellent handbook of practical, ably described and heuristically presented techniques. It assumes a degree of mathematical sophistication and knowledge which could be reasonably expected in a graduate (the first chapter summarising this information is too breathless to be didactic), treats linear optimisation fairly exhaustively, and makes extensive inroads into non-linear theory. Space is also found for sensitivity analysis and the last chapter on "Additional Topics" includes stochastic estimation and real-time parameter identification.

P. E. Roe

obituary

Arne Westgren, a pioneer in the application of X-ray diffraction to physical metallurgy, and also well-known for his X-ray crystallographic work in other fields of inorganic chemistry, died in Stockholm on March 7, at the age of 85.

Westgren started his academic career in Uppsala as a pupil of The Svedberg and in 1915 obtained the doctoral degree with a thesis on Brownian movement. While employed as a metallurgist at the ballbearing company SKF, he was confronted with several problems which he thought could be solved by X-ray diffraction methods, and found that the α–β transition in iron was not accompanied by any structural change, whereas γ iron showed the same cubic face-centered structure as the austenitic steels at room temperature. These successful results gave Westgren an appointment at the Institute for Metal Research in Stockholm in 1921, where he began an extremely fruitful collaboration with Gösta Phragmén. (Phragmén's great experimental skill resulted in the construction of very efficient X-ray focusing cameras). The studies of the iron modifications were continued and the structure of δ iron established. The unit-cell dimensions of cementite were also determined. In the copper–aluminium system a phase with the γ-brass structure was found for the first time, although its structure was not then solved. The structural analogies in the systems copper–zinc, silver–zinc and gold–zinc were found by Westgren and Phragmén in 1925. At about the same time they investigated the modifications of manganese and studied the carbide systems of chromium, molybdenum and tungsten. They also succeeded in characterising the 'high-speed' steel carbide. The structural analogies between the three systems copper–zinc, copper–aluminium and copper–tin, found by Westgren and Phragmén, gave more solid support to the rule proposed at the same time by Hume-Rothery, and founded on microscopial observations. In 1927 he was appointed Professor of General and Inorganic Chemistry at the University of Stockholm. This resulted in an increasing number of pupils, but nevertheless the collaboration with Phragmén lasted until the latter's death in 1944. The work on metallic systems continued, resulting in more complete structure determinations of phases as well as the solving of a considerable number of new structures. Extensive work on non-metallic systems was also carried out in Westgren's laboratory but was to a great extent performed by pupils of Westgren. In 1943 he was appointed Secretary of the Royal Swedish Academy of Sciences, and from that year only had time to turn to X-ray crystallography in leisure moments. He retired from this last appointment in 1959. Westgren also served as Secretary to the Nobel Committees for Physics and Chemistry from 1926 to 1943 and he was Chairman of the Committee for Chemistry from 1944 to 1965.

announcements

Awards

The prizewinners of the **Feldberg Foundation Awards** are **H. G. Wittman** and **J. B. Gurdon, FRS.**

The Chemical Institute of Canada has announced the following awards: **Fisher Scientific Lecture Award** to **S. Barabas** (application of automated chemical analysis in industry); **Montreal Medal** to **B. B. Migicovsky** ("leadership in the profession of chemistry"); **Merck, Sharp & Dohme Lecture Award** to **L. D. Hall** (synthesising novel carbohydrate derivatives and developing heteronuclear magnetic resonance spectroscopy to study organic compounds in solution); **Noranda Lecture Award** to **B. R. James** (contributions to physical and inorganic chemistry by a scientist under 40); **Chemical Education Award** to **W. E. Harris** (modernising university teaching of analytical chemistry).

The National Acadamy of Sciences (Washington) has announced the following awards: **James Craig Watson Medal** to **G. M. Clemence** (independent derivation of a new analytical theory of the motion of Mars); **John J. Carty Medal** to **J. T. Wilson** (theory of plate tectonics); **Henryk Arctowski Medal** to **J. M. Beckers** (discovery and study of exotic small-scale phenomena in the Sun); **Steel Foundation Award** to **B. M. Alberts** (isolation of proteins required for DNA replication and genetic recombination, and interaction thereof); **Award for Environmental Quality** to **J. T. Middleton** (adverse effects of photochemical air pollution in agriculturally important plants); **Arthur L. Day Prize** to **D. H. Matthews** and **F. J. Vine** (theory of plate tectonics); **Benjamin Apthorp Gould Prize** to **Lodewijk Woltjer** (Crab Nebula and galactic magnetic fields); **H. P. Robertson Memorial Lectureship** to **M. Rees** (high energy astrophysics and theory of quasistellar sources, radio galaxies and X-ray sources).

H. Marion and **G. Mahfouz** have been awarded **Telford Gold Medals** by the Institution of Civil Engineers for their paper 'Design and construction of the Ekofisk artificial island.'

The Royal Society has announced the election of the following as **Foreign Members: H. Gilman** (organometallic compounds and their reactions); **M. Heidelberger** (antigen–antibody interactions and structure of bacterial polysaccharides); **F. Lynen** (intermediary metabolism and enzyme action); **L. Onsager** (statistical physics and chemistry).

L'Académie des sciences, Paris, has elected two foreign associates: **Albert Claude** (Belgium), the winner of the Nobel Prize for Medicine in 1974; and **Joseph Doob** (United States), the mathematician.

Miscellaneous

Research on cancer. The International Union Against Cancer is supporting the Eleanor Roosevelt Fellowships, intended for experienced investigators carrying out independent research at a single institution in another country. Applications and further information (by September 1): International Union Against Cancer, PO Box 400, 1211 Geneva 2, Switzerland.

International meetings

June 23–24, **Scientific and engineering secondary information transfer for developing countries,** Brussels (General Secretary, ICSU AB, 17 rue Mirabeau, 75016 Paris, France).

July 3–10, **International botanical congress,** Leningrad (XII International Botanical Congress, 2 Professor Popov Str, Leningrad 197022, USSR).

July 6–10, **Underwater physiology,** San Diego (Secretariat, 6th Symposium on Underwater Physiology, 9650 Rockville Pike, Bethesda, Maryland 20014).

July 6–11, **Pure and applied chemistry,** Jerusalem (Organising Committee, 25th Congress of the International Union of Pure and Applied Chemistry, POB 16271, Tel Aviv, Israel).

July 6–11, **Nuclear magnetic resonance spectroscopy,** St Andrews, Scotland (Dr J. F. Gibson, The Chemical Society, Burlington House, London W1V 0BN, UK).

July 7–11, **Plant pathology,** London (The Director, Commonwealth Mycological Institute, Ferry Lane, Kew, Richmond, Surrey, TW9 3AF, UK).

July 8–12, **International committee on laboratory animals,** Thessaloniki, Greece (Dr N. Simionescu, Yale University School of Medicine, Cell Biology Department, 333 Cedar Street, New Haven, Connecticut 06510).

July 8–12, **Phonon scattering in solids,** Nottingham, UK (The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

July 10–11, **Autoradiography,** Edinburgh, UK (Dr J. Jacob, Department of Genetics, West Mains Road, Edinburgh EH9 3JN, UK *or* Dr T. Appleton, Physiological Laboratory, Cambridge CB2 3EG, UK).

July 10–12, **Inflammation,** Nottingham (Dr Alma B. Simmonds, Chelsea College, University of London, Manresa Road, London SW3, UK).

July 13–18, **Enzymatic and homogeneous catalysis,** Santander, Spain (Dr A. O. Ballesteros, Departamento de Catálisis, CSIC, Serrano, 119 Madrid-6, Spain).

July 13–18, **Clinical chemistry,** Toronto (Dr F. H. Sims, Chairman of the Publicity Committee, Women's College Hospital, Toronto, Ontario, Canada).

July 13–18, **Chemotherapy,** London (Conference Services, 43 Charles Street, London W1, UK).

Are the art treasures and the overseas students safe?

LAST week it was Mr Reg Prentice's turn, as Secretary of State for Education and Science, to appear at the House of Commons Select Committee's hearing on the financing of scientific research in British Universities. To his sympathetic questioners he declared that the universities were marginally more able, twelve months ago, to bear cuts in their funding than were most other parts of the educational system. There had been a generosity in the staff-student ratio which could bear a little squeezing, but now that had been done, and he did not think one could any longer generalise on the ability of universities to stand further onslaughts. But perhaps some well-endowed establishments might sell off a few of their oil-paintings to tide them over the crisis. The British Antique Dealers' Association pronounced the idea "morally reprehensible".

If we are down to dusting off the art treasures, then we are also at the level at which some other appurtenances of university life are vulnerable. The committee has already had a nose around unproductive research without much in the way of enthusiastic response from its witnesses. Where it does seem to be generating some momentum of its own is on the issue of postgraduate students from overseas. Thus Mr Norman Tebbit asked Mr Prentice whether overseas students were not occupying too much of the "well found" floor space supported by the University Grants Committee (UGC) and hence the taxpayer. Mr Prentice gave the standard deadbat response that there were long-term diplomatic and commercial benefits to having overseas students here.

It was clear that there is a view on the committee not only that overseas students could be charged rather more for their time here but also that there are some cases where the benefits of having overseas students are mainly benefits to the sending countries. This view is helped along by two observations: first that there are departments, particularly in the applied sciences, where overseas postgraduates are in the majority and, second, that although nobody is questioning the concept of aid to developing countries through the provision of university education, a growing number of postgraduate places is being taken up by students from the developed world.

The concern is a reasonable one within many people's concept of what a university should be, and deserves serious attention. In the five years from 1968 to 1973 the number of those obtaining higher degrees (in all subjects) has grown steadily from around 10,000 to around 14,000 a year. (Roughly 40% of these degrees are doctorates.) While the number of Commonwealth higher-degree recipients has remained static at about 1,500, the numbers from other countries has doubled from 1,000 to 2,000. In 1973, 27% of all recipients of higher degrees were from overseas—in pure science 22%, in applied science 36%. About 60% of overseas students returned home after obtaining their degree. In the same year 376 first-degree British graduates went overseas for further education; this figure has declined from 538 in 1970. Most recent figures show that overseas students now account for 33% of postgraduates and applied sciences probably over 40%.

Britain gives more than she takes in higher education, and fairly clearly she has been giving more to students from developed countries in recent years. Is there a case for any control of numbers? The reasons normally advanced against the suggestion are not the most compelling.

Although it is true that the training of students here generates a lot of goodwill in academic, industrial and governmental life around the world, it would be difficult to demonstrate that this creates much in the way of hard returns beyond providing professors with a choice of venue for their sabbaticals. If postgraduate training increases sophistication in students, it must be assumed that they are unlikely to be swayed in the purchase of, say, some piece of equipment by the fact that they went to university in the country in which the makers are situated. And if a piece of equipment being considered is one with which they had experience when in Britain, it is entirely possible that it was imported into Britain or did not prove satisfactory (or both).

The diplomatic profit argument is no easier to sustain. Armies lead by Sandhurst-trained officers have been known to act in other than Britain's interests. Is there any evidence that London-trained ministers of trade, technology, communications, oil and so on look any more kindly on the country in which they obtained their postgraduate education? Any Harvard-trained minister in the British government who started favouring US business would soon be out on his ear.

There are two much better arguments for encouraging the flow of overseas students—one idealistic, one chauvinistic. On the idealistic plane, Britain supports universities because they are places of learning, and learning, even in the applied sciences, knows few frontiers. True, the man with the key patent will profit himself and his own country first, but the benefits very quickly flow to the users as well as the inventor. And the inventor will have had to dip into a truly international pool of knowledge. Thus talk of great new British inventions, so beloved of newspapers, is often meaningless. The more the international character of learning is stimulated by the interchange of people, the more broadly and effectively does the academic life operate. (But fewer Britons are going abroad for postgraduate education.)

On the chauvinistic level, every postgraduate who comes to Britain is potentially capable of making a significant intellectual contribution even within a three-year period—and many do. It is often forgotten that some do their best work when still a student, and this work is then immediately available in the British community. Besides which, many stay for the rest of their lives. □

ABBAS

Famine revisited

Recent reports from Ethiopia indicate that famine has again struck the pastoral population of the south. A year ago an article in Nature *made the case that the collection of objective information in droughts is of the first importance in planning relief operations. The London Technical Group has undertaken the design and conduct of such surveys in Ethiopia and elsewhere. In this article Julius Holt, John Seaman and John Rivers of that organisation discuss their observations made on the pastoralists and farmers of Harerge Province, South-east Ethiopia, in mid-1974 after the first wave of drought. They comment on the failure of relief efforts to prevent death and disruption when the rains again failed.*

POPULATIONS do not suddenly starve; but starving populations becoming sudden and dramatic news. The process leading to famine after a natural catastrophe is prolonged and complex and occurs against a background of endemic malnutrition and poverty. By the time a famine is internationally recognised it is already at or past its peak, and relief aid does not usually begin to arrive in significant quantities until the starvation crisis is over and the majority of famine deaths have occurred. Emergency aid is, moreover, disproportionately costly, and economic considerations therefore support the humanitarian reasons for investing in timely and informative surveys to warn of developing famines and to guide effectively in their relief.

A year ago, workers from the London Technical Group and the Medical Research Council Dunn Nutrition Unit described in *Nature* their experiences in the drought-affected areas of north-eastern Ethiopia, pointing out the need to develop standardised survey techniques both for rapid famine assessment and for monitoring the situation during the danger period. By that time the focus of the drought was no longer in the agricultural highlands of the north-east but had shifted to predominantly pastoral regions, particularly the vast rangelands of Harerge Province in South-east Ethiopia. Some reports of starvation emanated from that area as early as the end of 1973.

The importance of rapidly gained but systematic information had won increasing recognition among relief agencies. Members of the London Technical Group were invited by the Ethiopian Relief and Rehabilitation Commission to design and direct a survey of Harerge from May to July 1974, and the project was supported by UNICEF, USAID, Oxfam and Christian Aid.

The purpose of the survey was twofold: the most urgent objective was to discover as rapidly as possible the nutritional condition of the population, but it was also hoped that the information gained would form the basis of a longer-term surveillance scheme. The problems presented were not inconsiderable. The geography of the region to be surveyed was daunting, for Harerge, which shares an extensive border with northern Somalia, is larger in area than England but has an extremely poor road system. A highland ridge, supporting an agricultural population of some 2.2 million, cuts into a semi-desert lowland ('Issa and Ogaden) which is seven times greater in area, with a population in normal times of up to 0.5 million pastoralists. There was a profound lack of baseline data on the area, which made it impossible to relate the survey sample accurately to the population distribution and thus made it necessary to include a large retrospective element in assessment.

The logistical difficulties were greatly reduced by the provision of three helicopters by USAID which, with some ground transport, allowed survey teams to make overnight stays at 65 sample sites within a month. But the difficulties inherent in the lack of baseline data remained largely intractable, especially since the effects of the drought were at the time of survey less dramatically obvious than some had expected.

The survey of the nutritional status of more than 1,000 children showed that both pastoral and agricultural populations were generally in a poor nutritional state, but severe protein-energy malnutrition was exceedingly rare. During the preceding twelve months death rates reported to us for children, particularly those of pastoral groups, had, however, been far higher than any reasonable estimate of mortality in a developing country would lead one to regard as normal, and the current demographic picture supported these reports. It was clearly not possible to be certain of the causes of death, but we were satisfied that no epidemic had occurred, and there seemed no reason to doubt the statements of the people that the chief cause had been malnutrition.

Experience elsewhere had led us to suspect that we might indeed be faced with a population which had suffered a tragedy but which at the time of the survey would not exhibit signs of extreme undernutrition. Much of the enquiry was therefore directed to a rapid attempt to define the impact of the drought on food availability for the near future. The Ethiopian Ministry of Agriculture had reported patches of poor harvest in the highland areas of the province, with some serious losses among the cultivators of the lower hills. Local people reported extremely high losses of livestock (cattle, sheep, goats and camels) and systematic observations during the survey of livestock held by pastoral groups showed that herds and flocks held were at about the number which had been reported as the minimum necessary for survival in the area. Before the main 'Gu' (March–May) rains, which had occurred just before the survey, these had been in poor condition and their lowered milk production could well have caused much of the mortality.

But the problem had been compounded by the fact that grain prices had risen steeply, and the survey found that rises were particularly extreme in the Ogaden where grain had been unavailable in some markets at times during the year. The significance of this is that the pastoralists live not only on the produce of their animals but also by selling them in order to buy grain. At the time of the survey the combination of livestock losses, the fall in the cash value of animals and the rise in the cost of grain had reduced the effective wealth of many groups to less than 20% of the level of the previous year and to under 10% of that of times before the drought. During the height of the drought some animals had been unsaleable and herders had been forced to eat animals they were no longer able to keep alive. The nutritional implications of this are considerable: for example, a heifer sold for grain would normally buy at least 8 times as much food (in calories) as are available from its meat.

The survey showed that the physiological reserves of this population were low and that their economic reserves had fallen to a point which in many instances was not far from that of no return. In short, this was a highly precarious nutritional situation. But the implications for relief were problematic. Grain is the basic currency of relief for pastoral as well as agricultural populations. But the logistics and administrative difficulties of distributing grain to a mobile population have never been successfully solved. The scheme actually adopted relies on the encampment of groups round administrative centres, thus simplifying the transport of grain. The result is large congregations of women and children together with some aged people; the men continue to move with the animals. There are three inherent dangers in this: first, the threat of long-term disruption in the social lives of families and groups; second, the risk of epidemic disease in such large congregations; third, the possibility that groups will not arrive in centres in time to avoid some mortality. The temptation under stress for whole groups, including the men, to become entirely dependent in the long-term on grain hand-outs is of concern to the authorities, and has important implications for the future of the pastoral economy in an area where agriculture will not be a viable alternative at least for many years to come.

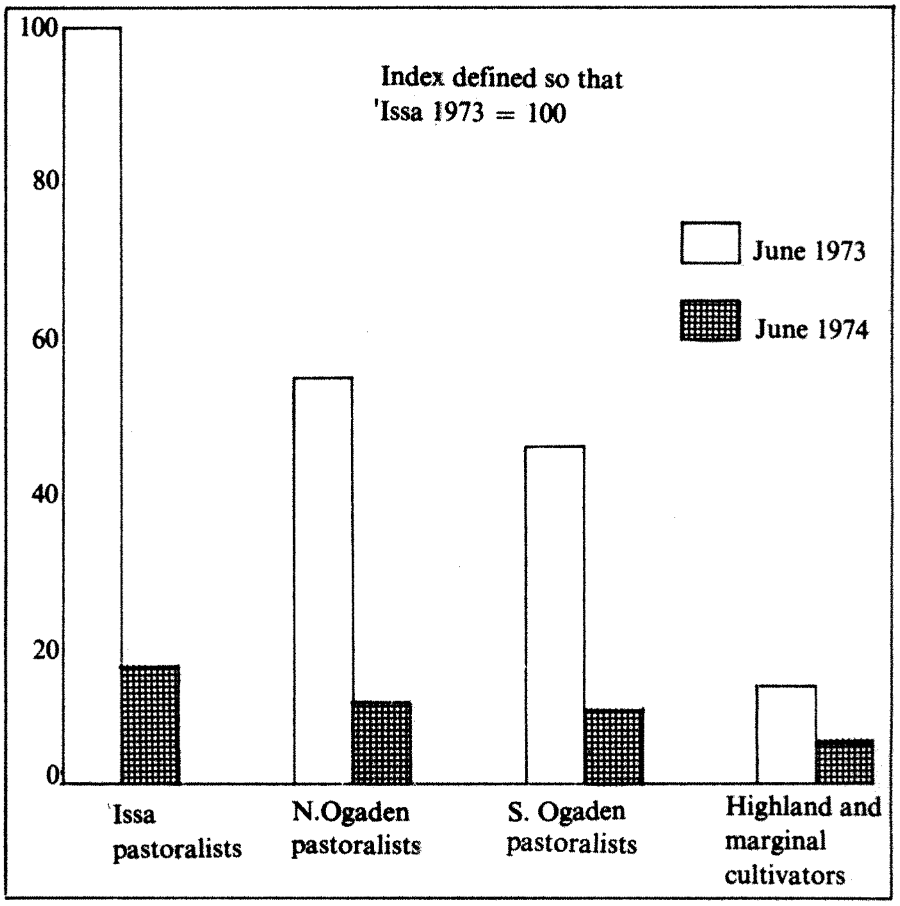
At the time of the survey we concluded that a further failure of the short rains in September–October 1974 was likely to be catastrophic for the pastoralists, whereas normal rains would allow them to take a vital step in strengthening their self-sufficiency. The recommendations, therefore, were that although resources should be husbanded for a major relief operation in the event of rain failure—by stock-piling grain and making provision for the large amount of transport which would be required—the other urgent priority at that time (July 1974) was the institution of a surveillance programme to monitor changes in the situation. Unfortunately the kind of sustained field-surveillance originally envisaged did not materialise. Meanwhile, a limited relief programme continued for the relatively small numbers of destitute people who were then clustered around centres.

In the event the autumn rains were sparse. Reports reaching us from the Ogaden in the first part of 1975 spoke of a deteriorating situation with numbers around relief centres (mostly women and children) growing to 50,000. A recent report from Oxfam cited a peak death rate in this group of 150 children a day, which, in spite of the efforts of medical teams, had not fallen below 50 a day by early April. Such numbers of people in such condition offer a disturbing indication that the linked problems of surveillance and effective relief there are far from overcome.

Most estimates of food availability in developing countries depend on ratios of estimates of crop yield and spoilage to estimates of population, and are subject to large errors. In particular, the sensitivity of such ratios as indicators of change is poor. Prediction of famine is only possible at the most general level by such techniques, and it is impossible to pick up the smaller local shifts between hardship and disaster. On the other hand, a comprehensive assessment of a famine situation has been shown to be possible using the kind of nutritional and socioeconomic measurements that formed the basis of the survey described here, with the special advantage that, provided care is taken with the sampling technique, the accuracy of the system is sufficient to indicate relatively small changes in the nutritional status of local populations.

Baseline surveys and the organisation of repeat surveillance should be considered a priority in those areas of the developing world which are now identifiably prone to extreme localised food shortages. This would not constitute a large diversion of resources. For instance, in spite of its size the Harerge survey cost, helicopters apart, less than £10,000. In subsequent surveillance of such areas the body of the work does not need highly trained personnel or a high capital investment in sophisticated equipment. The use of expensive air transport tends to be the price paid for belated reactions to an emergency. In any of the recent African droughts an effective field-surveillance programme could have been mounted for less than 1% of the cost of the total relief programme, and could have helped to ensure that for the first time aid arrived before people died of starvation. ☐

Purchasing power of animal herds in grain equivalents.



What kind of strategy for leprosy?

By S. G. Browne, Director of the Leprosy Study Centre, and T. F. Davey, of Leprosy Review.

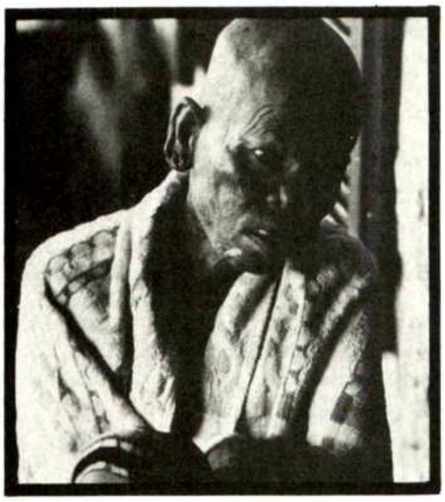
AN article by C. L. Crawford (*Nature*, March 20), stressed in vigorous terms the well recognised concept that the best available means of secondary prevention of leprosy lies in the regular and sustained treatment of leprosy sufferers with the cheap and effective mycobacteriostatic drug, dapsone. We agree, and have said the same, many times.

The well-night insuperable difficulties facing the World Health Organisation and voluntary agencies, in trying to implement a strategy on which they are now generally agreed, are concerned with factors to which Crawford seems to pay little attention in his article. These factors are, on the one hand, the social aspects of leprosy, their effect on government policy and priorities, and patient attitudes to leprosy, and, on the other, the inadequacy of diagnostic and curative facilities in precisely those countries where leprosy constitutes a major health problem. Add to this the long duration of treatment advised and the need for regularity of treatment—if deformity is to be prevented and the risk of drug resistance minimised—and the world situation can be seen in its stark reality, which is reflected in successive reports from the World Health Organisation and its Expert Committee.

Those of us who have been concerned for upwards of 40 years with mass treatment schemes for leprosy and ambulatory treatment/control measures integrated into the general urban–rural health services cannot but agree that "sulphones provide a cheap and practical form of treatment and also prevent transmission of leprosy". A recent editorial in *Leprosy Review* says the same thing: "The maximal extension of sulphone treatment, and a skilled sustained campaign of leprosy education are priorities for us all." The problem is to discover large scale schemes, adequately documented and supervised, in which this thesis can be conclusively demonstrated. An oversimplification of his case, illustrated by atypical populations with "a small leprosy problem" and highly selective official estimates of incidence rates, may not convince the cautious epidemiologist.

It would be a salutary exercise to expose the deficiencies in Crawford's article: "the mode of transmission and the incubation period are unknown"; "there is no . . vector to spread the disease"; "only one in ten of the exposed population, at the most, acquire the disease"; leprosy declined in Norway "by a policy of segregation"; "once eradicated from any country, it has never returned"; "no attempt has been made to obtain information about incidence rates"; "accurate figures of leprosy are available . . . in Rumania, Cyprus and Libya".

From recent personal observations, we consider that the conclusions drawn by Crawford regarding the situation in some of the countries he refers to are not in accordance with the facts; on the contrary, the total prevalence rates (comprising the accumulated back-log of high incidence rates associated with a virtual breakdown of rural health services) are much higher than they were 15 or 20 years ago. This does not, of course, invalidate his main thesis that regular and adequate sulphone therapy could eventually result in a reduction of incidence rates, but it does emphasise the realities of today's world and the intractability of the problems of the control of transmissible diseases, among which leprosy figures along with malaria, tuberculosis, trypanosomiasis, onchocerciasis, schistosomiasis and the rest.



Courtesy The Leprosy Mission

Crawford asserts that "drug resistance is very rare". It was, but it is not now, and the recent figures coming from countries where the problem has been adequately investigated are very disturbing, to say the least.

"In many (countries) the leprosarium remains the only place where treatment can be obtained". This statement is hopelessly out-of-date, as is the incredible assertion that, of the £2 million raised annually by voluntary agencies in Europe for leprosy work, most is still spent on institutional care. More than 900,000 leprosy sufferers are being treated at the moment through programmes assisted financially by these maligned voluntary agencies, and the vast majority of these patients are being treated in ambulatory schemes; in addition, about £250,000 a year is being devoted to leprosy research. About a third of all leprosy patients now receiving any treatment at all are getting it through these same voluntary organisations. If such mis-statements are allowed to pass uncorrected, a grave disservice will be done to the cause of truth and to the leprosy sufferer.

As for prophylaxis, to judge by the tempo of much cooperative research based on the availability of relatively enormous quantities of *M. leprae* obtained from experimentally infected armadillos, a specific vaccine should be produced in the not-too-distant future, together with a specific skin test. Chemoprophylaxis (with dapsone) has been shown to be effective, as Crawford points out, but here again the practical objections to large scale implementation are over-riding. Countries where such a measure might be justifiable on general grounds lack both the medical infrastructure and the finance, not to mention the cooperation of the population necessary over a prolonged period (possibly 3–5 years) during which the regular ingestion of a toxic drug by mouth (dapsone) or by intramuscular injection (acedapsone every 75 days) would be necessary.

Ministries of Health the world over are facing the problem of a chronic crippling disease, which, ideally and considered in isolation, might require a special service with vast resources—for diagnosis, laboratory cover, prolonged treatment (with a drug that is cheap, admittedly, but whose real cost is greatly enhanced by the expense of getting it to the patients who need it), preventive physiotherapy, provision of protective footwear, not to mention rehabilitation facilities. The social and medical dangers of over-emphasising one of the endemic diseases lie in creating or perpetuating the idea of 'uniqueness' and 'difference' and hence encouraging the stigma attached to the disease.

If treatment of leprosy could be rapid as well as cheap, unaccompanied by severe episodes of reaction as well as effective, capable of bacillary clearance as of mycobacteriostasis, then Crawford's fundamental thesis would be gladly accepted by governments. Meanwhile, inadequately staffed and inadequately financed health services in many countries in the Third World, while awaiting a more effective strategy of control based on primary prevention of leprosy, are striving with varying degrees of enthusiasm and success to put into practice the principles of secondary prevention based on the availability of a cheap and reasonably effective drug, dapsone. ☐

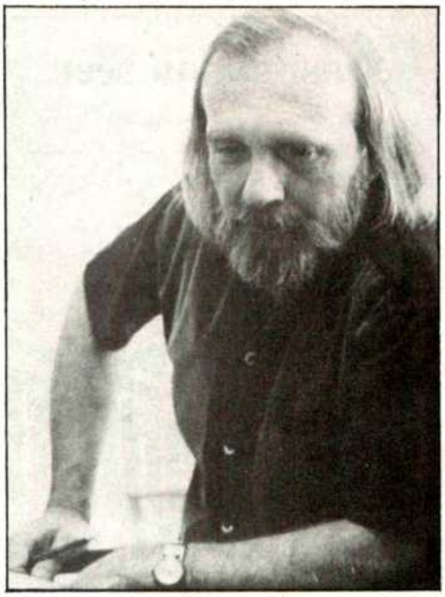
Scientific freedom and responsibility

by Colin Norman, Washington



Tamplin: troublesome scientist

DURING the late 1960s, two scientists employed by the Atomic Energy Commission (AEC), John Gofman and Arthur Tamplin, launched a public attack on the AEC's regulations governing permissible standards of exposure to ionising radiation. They contended that the regulations were too lax because people exposed to radiation at the permitted levels would run an unacceptable risk of developing cancer. The AEC responded in kind with a vigorous public defence of its regulations. But, according to Gofman and Tamplin, it also responded with a private attack on its two troublesome scientists — it greatly reduced their laboratory budgets and staffs.

That episode highlights a problem which has been cropping up with increasing frequency, namely, how can scientists who feel a moral obligation to speak out on particular issues do so when such actions place them in direct conflict with their employers or with other powerful vested interests? And that particular episode also provided a catalyst for the establishment by the American Association for the Advancement of Science of a committee to investigate such conflicts.

The commitee's report finally appeared last week after an inordinately long gestation period of 4½ years. Written for the committee by John T. Edsall, a Harvard biologist, it stands out as a thoughtful and eloquent statement on academic freedom and scientific responsibility—a field which has all too frequently been a subject of much academic claptrap.

First, Edsall discusses some of the moral and ethical concerns which have arisen among scientists themselves over a few areas of research, and which could result in restrictions on academic freedom. Noting that "the basic function of the scientific community is the advancement of knowledge", he suggests that some scientists "might well believe that nothing should be off limits as a possible subject for basic research, as distinct from applied science and technology". But he reckons that "there may be strong reasons for declaring certain areas of research off limits, or at least for imposing severe restrictions on them".

Some types of experiment on human subjects, for example, "raise serious questions" and should be carried out only according to strong ethical and practical guidelines which may inevitably rule out some of the more dangerous activities. Moreover, the recent call for a temporary halt in some types of genetic manipulation experiments was "a landmark in the assumption of scientific responsibility by scientists themselves for the possible dangerous consequences of their work".

But, on more controversial ground, Edsall offers a strong defence of the legitimacy of research into the role of genetic factors in human intelligence. It has been argued that such research should be declared out of bounds because it could exacerbate racial prejudices. But Edsall strongly supports "the view that inquiry into genetic differences between racial groups is a thoroughly legitimate field of research, and we condemn the emotional attacks that have been made against such persons as Arthur Jensen and R. J. Herrnstein, because of their views concerning the importance of genetic factors in human intelligence. Their views are, of course, open to critical debate and challenge on scientific grounds, as long as the debate is conducted on an objective scientific level".

The problem, however, is that once such views enter the political arena, the debate automatically leaves the "objective scientific level", and the real question is what responsibility scientists should have for the uses to which their research findings are put. On the particular question of racial differences in intelligence, Edsall offers only the suggestion that "it is wise for investigators to state their results cautiously and modestly, to specify clearly the limits of accuracy, and to refrain from sweeping claims based on highly specialised researches".

As for conflicts which arise when scientists blow the whistle on their employers or make public statements on scientific issues which place them in conflict with vested interests, there are many examples of the subjection of scientists to professional harassment for trying to defend what they see as the public interest. The case of Gofman and Tamplin is one example. Another is the case of three engineers working on San Francisco's Bay Area Rapid Transit System. In 1972, they were summarily dismissed, allegedly for making statements about defects in the train control system—statements which later turned out to be correct.

There have also been occasions when scientists working for industrial concerns have sided with the company in suppressing data damaging to their employers' operations or in resisting changes which would result in more rigorous health and safety standards.

In such instances, Edsall argues that professional societies should play a much more active role in defending the interests of their members or in adjudicating in disputes where issues of scientific freedom are involved. The societies "can deal with such issues by setting up committee of inquiry, in cases where a serious violation of scientific responsibility is suspected; by publicising the results of the inquiry in professional journals, and, if necessary, in the more popular journals and in the news media; and by calling the matter to the attention of governmental bodies", Edsall suggests, and he adds that "they can on occasion launch law suits on behalf of members who have apparently suffered injustice when acting on behalf of the public interest".

Although such activities may raise serious problems of funding and thus would require individuals to spend substantial amounts of time serving on hearing panels, Edsall reckons that "increased activity of the professional societies [is] the most hopeful approach to the problem in the immediate future". □

Washington seen

A SET of figures, published last week by the Department of the Interior, casts further doubts on the ability of the United States to shake off its dependence on imported oil. The department has drastically reduced its estimate of the amount of recoverable oil and gas that remains to be discovered in the United States and the new figures suggest that domestic resources could be severely depleted within about 30 years.

The new estimates are close to those published earlier this year by a committee of the National Academy of Sciences, on the basis of which the committee concluded that "US independence from external sources [of oil and gas] is essentially impossible on the basis of increased production of petroleum during the next decade".

The Department of the Interior now estimates that there are between 50×10^{9} and 127×10^{9} barrels of oil and between 320×10^{12} and 655×10^{12} cubic feet of natural gas yet to be discovered within the United States and, in deposits offshore. In addition, it reckons that about 30×10^{9} barrels are recoverable from unexplored parts of existing fields.

Those figures stand in sharp contrast to estimates published a year ago which suggested that undiscovered oil reserves amount to between 200×10^{9} and 400×10^{9} barels; gas reserves were put at between 990×10^{12} and $2{,}000\times10^{12}$ cubic feet. Moreover, in 1972, the Department of the Interior was predicting that undiscovered recoverable oil reserves amounted to 458×10^{9} barrels. Those earlier estimates have, however, come under sharp attack from the oil industry because they were based on allegedly unrealistic estimating techniques, and the new estimates are derived by a method which the oil companies—and the committee of the National Academy of Sciences—believe is more accurate.

If the new estimates turn out to be correct, they hold a number of very important implications for energy policy in the United States. First, they dramatically underline the need for increased conservation of oil and gas. And, second, they make more urgent the need to develop replacements for natural gas and petroleum, such as synthetic fuels produced from coal. As Dr Vincent E. McKelvey, Director of the US Geological Survey, which developed the estimates for the Department of the Interior, put it last week: "[they] show that it is necessary soon to develop other sources of energy as the mainstay of our future energy supply".

● In a move hailed as a major victory by environmentalist organisations and as a major tragedy by nuclear power industry, the Nuclear Regulatory Commission (NRC)—which recently assumed the regulatory functions of the defunct Atomic Energy Commission—has announced that it will postpone, for up to three years, a final decision on whether plutonium will be allowed as a fuel for nuclear power plants in the United States.

Plutonium, which is a by-product of the fission reaction in nuclear power plants, could be recycled as a nuclear fuel to help eke out domestic supplies of uranium in the United States. The former Atomic Energy Commission had hoped to make a final ruling this year on whether or not plutonium recycling should be allowed, but the NRC has now decided that the whole matter should be the subject of public hearings.

According to critics and supporters of nuclear power alike, the NRC's final decision on plutonium recycling will be crucial to the development of the nuclear power programme. For one thing, plutonium recycling would more than double the amount of energy which could be extracted from a given amount of uranium and it would therefore help hold down the costs of electricity production. And, for another, part of the justification for the breeder reactor rests on the fact that he plutonium produced in breeders would be used to fuel light water reactors. As Thomas Cochran, who works for the Natural Resources Defense Council, pointed out last week, "the breeder programme would look a bit silly if plutonium were banned as a fuel in light water reactors".

The chief objections to plutonium recycling are that it would involve transporting large amounts of plutonium around the United States. Since plutonium is highly toxic, and since it could be used as the core of a nuclear explosive, opponents have argued that plutonium recycling would increase health hazards and greatly elevate the risks that a terrorist group could make off with a few critical masses of potential bomb material.

Environmentalists are pleased with the NRC's decision to hold public hearings before making a final ruling, because they are convinced that the delay will allow opposition to increase. The nuclear power industry, on the other hand, is less enthusiastic. Mr Carl Walske, President of the Atomic Industrial Forum, last week called the decision "ironic and deplorable", particularly in view of the Interior Department's recent drastic reduction in its estimates of oil and gas reserves in the United States.

The decision to postpone a final ruling on plutonium recycling may, however, turn out to be a shrewd political move on the NRC's part. It was the first major decision taken by the commission, and by opening up the issue to further public debate the NRC has served notice that it is prepared to take a tough stand in spite of vocal opposition from the nuclear industry. Its predecessor, the Atomic Energy Commission, was constantly accused of promoting the nuclear industry instead of regulating it.

● The National Aeronautics and Space Administration is moving into the final stages of planning a space mission to Uranus in the 1980s. Last week, NASA invited scientists to propose experiments for the mission, which would probably be launched in 1979, swing past Jupiter in 1981 and reach Uranus in 1985.

As now planned, the mission would use a Mariner-type spacecraft, which would pass Jupiter at a distance of about 392,000 kilometres and come as close as 24,000 km to Uranus.

Because Uranus has many interesting and enigmatic features—such as the fact that it spins on its side and its atmosphere seems to contain large amounts of methane—the mission has strong support among space scientists. But, earlier this year, the National Academy of Sciences suggested that NASA should reconsider the mission's priority in light of the fact that the space science budget is unlikely to grow much, if at all, in the coming year. Officials of NASA believe, however, that the mission could be fitted into the budget for two reasons. First, it will rely partly on existing hardware, which will keep the costs down and, second, the major expenses will be incurred before the most expensive development phase of other space missions such as the Large Space Telescope and a possible Jupiter orbiter mission.

Porton lab will study fever virus

by Eleanor Lawrence

THE new laboratory at the Microbiological Research Establishment, Porton Down, formally opened last week by Lord Godber, provides facilities unrivalled in Western Europe for the safe handling of the most dangerous viruses known.

The new facilities will be used first to study the Lassa fever virus, and the other haemorrhagic fever viruses which have mainly been discovered within the past ten years and are virtually untreatable.

Porton, with a long history of handling some of the most dangerous organisms known to man was the obvious location for such a centre. The new laboratory was started two years ago, and has been modelled on facilities at the Communicable Diseases Center at Atlanta, Georgia, which, until now, was the only laboratory considered sufficiently secure to handle the Lassa fever virus.

The first task of the laboratory will be to build up a bank of diagnostic sera against the rare haemorrhagic fevers, such as Bolivian and Congo haemorrhagic fevers, and other exotic tropical virus diseases, such as Marburg disease, that may be brought into the UK. It will also provide this facility for other European countries and, in conjunction with Atlanta, for the areas where these diseases are endemic.

Lassa fever (first recognised in Nigeria) seems to be one of the most virulent virus diseases yet discovered. The mortality in Europeans with diagnosed Lassa fever is around 48% (although it seems to be lower in the native Nigerian population). It is also one of the most infectious virus diseases known. Patients shed virus from all body secretions and through the respiratory tract, and specimens of blood and urine are heavily infected. When the virus is multiplied up in tissue culture or in experimental animals, the risk of infection is greatly magnified.

Apart from its primary use in dealing with the virulent tropical viruses which may be carried into the UK undetected at any time by people returning from abroad, the laboratory will undoubtedly be in demand from research workers wishing to carry out some of the more potentially dangerous genetic engineering experiments in which the DNA of bacteria or viruses is modified by the addition of foreign DNA from other bacteria, viruses or even higher animals. Professor Robert Harris, the Director of Porton, said last week that he had been approached by the Ashby Committee and had argeed that the laboratory facilities could be placed at the disposal of research workers wishing to undertake such experiments, but that he had not yet received any specific proposals. As the laboratory is sufficiently secure to satisfy the most stringent criteria set down by the recent conference called by Professor Paul Berg in California early this year, proposals will probably not be long in materialising.

The Berg conference recommended that experiments in which hybrids of two different viruses were made, or virus DNA (or DNA transcribed from RNA viruses) was linked to bacterial plasmids to multiply up virus genes, or mammalian DNA was linked to bacterial DNA could be carried out under conditions slightly less stringent than those in the new laboratory at Porton but that where the hybrid or the starting organisms were virulent or likely to prove so, the maximum security precautions should be taken. The other proviso of the Berg recommendations was that genetically enfeebled strains should be used.

But the prime object of the new facilities is the identification of the rare but virulent tropical viruses, which pose not just a potential but an actual public health hazard. With aeroplanes bringing their human and animal cargo into European airports every day from the tropics, the possibility of an epidemic of one of these virulent untreatable viruses cannot be discounted.

The only specific therapy which has proved effective against Lassa fever is serum taken from a convalescent patient. But with only three Europeans having recovered from the disease, the supply of convalescent serum is extremely limited. Also, administering convalescent serum from a newly recovered patient can be extremely risky as virus is excreted from the patient for several weeks after clinical recovery. One aim at Porton is to establish a bank of safe serum, either from convalescent patients or from the naturally resistant native population, which can be given to patients once the disease has been diagnosed. □

SCIENCE PAGE

WHAT THE SCIENCE PAPERS SAY......

PRECISION WARFARE. Novel weapons guided by lasers, TV and other homin systems could change the nature of warfare. NEW SCIENTIST, May 9.

BETTER SILK WORMS. According to a report in NATURE (May 8) a "better" silk worm, in commercial terms, is a male. Genetic engineering offers ways of breeding more males.

THE BBC has been providing at first 24 and now 50 televised "pages" of printed material by using spare lines in the ordinary BBC 1 TV channel since last September; the service (code-named CEEFAX) is soon to be increased to 100 pages, and a similar service (called Oracle, but using the same standard technology as CEEFAX) will be provided by the Independent Broadcasting Authority (IBA) from next month. Until recently, the cost of a decoder to enable these printed words to be read on an ordinary television set has been prohibitive—at least £300 for a custom-made box of electronic tricks. But last week Texas Instruments, Bedford, announced in London that they will be producing appropriate decoders on a production-line basis by early next year, when they should be available for about £50. A television set with such a decoder built in at the construction stage should then cost about £100 more than an equivalent set without a decoder, and the industry hopes that prices will fall.

As well as newsflashes, sports results, a science page (see above), weather maps and other services already available from CEEFAX, this new technology opens up intriguing possibilities. Using telephone links and a keyboard, this kind of 'teletext' could help to create a home computer terminal, and there are obvious potential applications in education.

Trying to get MPs interested in science

from David Spurgeon, Ottawa

FIVE years ago, when interest in science policy was still running high among some Canadian scientists and politicians, the Association of the Scientific, Engineering and Technological Community of Canada (mercifully shortened in popular parlance to SCITEC) was formed. It was established in response to the frustrated complaint of a member of the Senate Special Committee on Science Policy that he could not determine which among the many voices really spoke for science in Canada. It was to become a sort of 'parliament of science', and one of its main purposes was to initiate a dialogue with members of the real Parliament in Ottawa.

Since those palmy days, science policy discussions have fallen upon such bad times that when SCITEC recently held its fifth annual meeting, one parliamentarian summed up the present situation thus:

"Science policy is the biggest non-question in the House of Commons. Nobody even knows how to frame a question. On occasions I have been asked to please ask a question of the science minister. Nobody even knows he's there, and a politician can stand anything except not being noticed."

Max Saltsman, New Democratic Party member, had been invited as a member of a panel held after the annual meeting to initiate between parliamentarians and scientists, just the kind of dialogue both have found lacking in the past. The report of the outgoing association president, Dr M. P. Bachynski, said it was SCITEC's intention "that this become a continuing dialogue which could lead to a more formalised vehicle for such interaction —an association of scientists, engineers and parliamentarians."

This hope reflected an earlier one, expressed years ago when the organisation had just got going, that an informal club might be formed for the same purpose. Under the circumstances, the hope seemed rather a forlorn one.

But at least a dialogue had begun. Most of the MPs on the panel, of course, might have been expected to be interested, because they had scientific or engineering backgrounds. They included Harvie Andre, a Progressive Conservative MP with a PhD degree in chemical engineering, formerly an associate professor in that discipline; Frank W. Maine, Liberal MP and former Athlone Fellow, who holds a PhD in organic chemistry and was previously director of research and development in a manufacturing company; and Ross Milne, Liberal, an engineer with a master's degree in environmental control.

Mr Andre was particularly concerned with the present state of public policy relating to science: he called it "a hell of a mess." Recalling the great interest in science policy during the 1960s, he said this had led to an uncomplimentary comparison of Canada's performance with that of other industrialised countries. A whole series of studies had shown that Canada spent proportionately less on research and development than most industrialised nations, and spent less on such activities in industry and more on in-house government research.

The response of the federal government was to create the Ministry of State for Science and Technology (MOSST), but that did not solve the problems, Mr Andre said. "In the four years that department has been in operation, in every way, in each of those [four] areas of comparison, we are worse off." Canada now spends a smaller percentage of its GNP on science and technology; in spite of the MOSST's contracting-out policy, the proportion of in-house research and development has increased rather than decreased (from 65 to 72% of the total); and the percentage of the GNP spent on research and development by industry has about halved.

Mr Andre said he was not implying this was all the MOSST's doing. He felt rather that the ministry lacked muscle to accomplish its objectives. He would like to see it obtain that power—if not, it should be abolished. "It is now a convenient screen to divert attention away from problems and it allows the government to say they are curing the problems."

Dr Virginia Douglas, immediate past president of SCITEC and a panel member representing science, said politicians and scientists both seem to agree that they must get together, yet they also seem to agree that, after endless studies, "we've achieved little communication."

She suggested the trouble was that the two groups work from different assumptions and use different techniques to solve problems. She said the mission-oriented approach is understandably attractive to politicians, but many others are not convinced that a direct, simple-minded approach will solve society's problems. Scientists are being asked to provide simple answers for complex questions—sometimes insoluble ones. And not everything can be subjected usefully to cost-benefit analysis, as politicians would like.

The attempt to control science and put it to work through bureaucracy does not seem to be working, she said, and it endangers the productivity of science. She pleaded with the politicians not to put scientists into a bureaucratic strait-jacket and not to put them into the position of being adversaries. And she said the time has come to stop talking abstractly about policies and start adopting a case approach to the solution problems.

Perhaps one of the best indications of the parlous state of relations between SCITEC and the federal government was revealed in Dr Bachynski's report on SCITEC's attempt to obtain approval of a plan to build a house of science and technology (HOST) to bring together the mostly indigent scientific societies centrally in Ottawa.

The MOSST had never answered the proposal officially, Dr Bachynksi said. But unofficially, the indications were tha the ministry would not support it as SCITEC wanted. "The impression I have is that the ministry would be glad to support such a project as long as it didn't cost the government any money."

Money, of course, was exactly what SCITEC and the other societies needed. But, according to Dr Bachynski, the ministry seemed to think that it would be a difficult idea to sell politically, because all kinds of other groups might then want similar favours and the electorate would not see why scientists should be treated any differently from anyone else. A perfectly understandable view, one is tempted to add. □

Clearing house for cancer epidemiology

THE International Agency for Research on Cancer of the World Health Organisation in Lyon is collaborating with the Deutsches Krebsforschungszentrum in Heidelberg in setting up an international clearing house for the exchange of information on epidemiological studies in cancer. Requests are just going out to epidemiologists to complete a standard form describing the on-going projects. It is hoped that in this way an Annual Directory can be compiled and also that participants can be supplied with current information at any time. The sponsors believe that this may, among other things, help cut down the number of occasions on which similar studies cannot be campared because some relatively minor procedure was not carried out in all cases.

Soviet diary

from Vera Rich

THE publication in the United States last week of tapes purporting to reveal the "last hours" of Colonel Vladimir Komarov, who perished aboard Soyuz 1, can hardly be considered an auspicious augury for the forthcoming Soyuz–Apollo programme. The tapes raise the whole problem of credibility and completeness of information exchange between the Soviet and American participants.

According to the tapes, the Soyuz was out of control for some 12 hours before the disaster, with Komarov fighting desperately to retain control (taking time off, however, for a farewell to his wife and child, and a talk with Premier Kosygin). According to the official Soviet releases, the flight proceeded normally until the moment of deployment of the parachutes. The Tass communique (April 25, 1967) stated: "After implementation of all the operations connected with transition to the landing regime, the ship successfully completed the most difficult and responsible braking sector in the dense strata of the atmosphere, and fully decelerated from the initial orbital velocity. However, when the main parachute was opened at an altitude of 7 km, a twisting of the parachute lines, according to preliminary data, caused the ship to descend at a great speed which resulted in V. I. Komarov's death".

An article by Yuri Gagarin, who was present at the control centre during the whole re-entry procedure, said much the same. The flight was perfectly normal, he maintained, until the moment when the parachutes should have opened. He described the shock felt by all in the control centre when this last-minute disaster occurred. Gagarin's article appeared in *Komsomolskaya Pravda*, the newspaper of the Young Communist movement (young, in this context, meaning 18–35 years)

Certainly, a number of Western commentators at the time suggested that the spacecraft had been out of control for some time before re-entry —these commentators, however, seemed motivated by a preconceived idea that, since "Soyuz" means union, Komarov's craft was meant to be a participant in a manned link-up, but that difficulties with his craft led to the cancellation of the (presumed) second launch and his "premature" re-entry after only 18 orbits.

Another mystery is the state of Komarov's health A background article in *Pravda* of April 24, 1967, which had gone to press before the disaster, stated that after the flight of Vostok 4 (for which he was back-up for Popovich), he had developed a heart murmur, but "a good rest, a more sensible everyday regime, self-confidence and the moral support of his comrades did their work", so that a later medical board found nothing wrong with him, and he was able to make a 24-hour orbital flight in October 1964 Before the flight of Soyuz 1, said this article, he had received "the highest rating". Certainly, it would seem unlikely that any space programme would launch a man in less than perfect health—yet some medical reports which seem to have been written for limited circulation among Soviet experts in space medicine seemed to imply that the proximate cause of the disaster was that Komarov lost consciousness at a crucial moment during re-enry, implying either that the parachute system had to be deployed by a manual control (out of key with the whole tenor of the Soviet space programme, which places so much emphasis on automation that the early cosmonauts were virtually no more than human test animals) or else that, being unconscious when disaster struck, he was unable to make some last minute effort to save himself.

● One of the contributions of the Byelorussian SSR in the current five-year plan is an extensive programme of the study and conservation of the flora and fauna of the republic. This included the launching of a new popular science journal *Rodnaya Pryroda* (Our native nature), research projects by the various scientific institutes of the republic, and a special prize for the best coverage in the media of the problems of conservation. The programme was clearly aimed at local loyalties and sentiment, with extensive use of the Byelorussian language (although current Soviet policy favours the "unifying" importance of Russian).

According to reports in *Rodnaya Pryroda*, the programme is making excellent progress, no less than 13 of the 48 scheduled "themes" being completed three years ahead of schedule. In at least one respect, however, all is not well with conservation in Byelorussia—the close season for fishing is not being respected During the spawning season, persons unspecified are "barbarously" fishing for shallow water fish, to the great detriment of the fish reserves of the republic.

To combat this, "all possible forces" are to be mobilised, ranging from the Fisheries Board of the Council of Ministers of the Byelorussian SSR, through the Byelorussian Conservation Society and the Society of Hunters and Fisherman, down to school-children and the "pioneers" youth organisation. How, precisely, they are to combat the poachers is not explained—presumably by some attempt at patrolling the numerous lakes and rivers of the aquiferous republic. What is more puzzling is who is doing the poaching at all. Byelorussia is not rich in natural resources, and has a long peasant tradition of cautious preservation of the little that is available. Although the new great oil refineries at Novo-Polotsk and Mozyr have brought in many workers from all parts of the Soviet Union, it would be too naive a solution to attribute the depredations to oilmen having a quiet day's angling. The most probable answer seems to be that of 'deculturalisation'—that state planning and state control have destroyed the old, careful traditions, and that rules of conservation which were once an integral part of local tradition now have to be reimposed, by official decree.

● The idea of recovering gold from the sea is not a new one. But attempts to date have all proved uneconomical—the value of the metal recovered being less than the cost of extraction. Now, however, data from the recent Atlantic voyage of the research vessel Mikhail Lomonosov have reopened the question of extracting gold from seawater. Analysis of deep-water samples indicate a gold concentration some 1,000 times higher than expected—a value which, if confirmed for a sufficient number of sites, might well indicate that the metal could be extracted commercially.

The reasons for these high concentrations are as yet a mystery and, not surprisingly, the sites of these anomalies have not been revealed.

● A new means of producing extra-strong concrete has been developed at Naovi (Uzbek SSR)—dropping it This, according to the inventor, Candidate of Technical Sciences A. K. Brovtsyn, produces "complex physico-technical interactions between the grains of the filler and the cement particles", giving an increase in strength of up to 15% A pilot plant for dropping concrete components of up to 3 tonnes in weight on to an elastic base from a height of 35 cm has been developed at a cost of 2,000 roubles (£1,000).

● An artificial method of producing triplets from single-yoked eggs has been demonstrated by embryologist, German Svyatogor of Leningrad University. The method consists of surgically opening the egg, dividing the blastocyst with a micro-scalpel, and then resealing the egg. So far, the Novosti agency reports, triplets have been successfully produced, from the eggs of hens, ducks, turkeys and Japanese quail

correspondence

LEPRA'S money

SIR,—In writing on leprosy (March 20), Dr Crawford claims that the numbers on treatment have remained low for the reasons he mentions and not for lack of money, as LEPRA claims.

The cost of maintaining patients in institutions is enormously high and LEPRA recognised this in 1963 when it carried out a reappraisal of its work. Consequently it has not for many years given grants for maintaining patients unnecessarily in institutions, but still maintains that the numbers on treatment have remained low because of a lack of money, as the cost of finding patients and ensuring their regular treatment on a domiciliary basis for at least three years is very high.

Dr Crawford concludes his article with an accurate example of how LEPRA is using a very small proportion of the money given to it, for a specific purpose. His example, however, may have given your readers an inaccurate picture since the example suggests that voluntary agencies in Europe are still spending most of their income on institutional care This is not the case with LEPRA since its contribution to the fight against leprosy in 1974 was:

- £210,000 on leprosy control projects, mainly for domiciliary treatment.
- £66,000 on grants to encourage early diagnosis for domiciliary treatment of children suffering from leprosy.
- £10,500 on leprosy research.
- £6,600 on training.
- £6,500 on the leprosy aspect of multipurpose rural health projects.

G. F. HARRIS

LEPRA, Colchester, UK

HTRs, zink and aluminium

SIR,—The high temperature gas-cooled reactor (HTR) has frequently been suggested as a source of process heat for steel-making, but we suggest that it could also be used in the zinc —and aluminium—making processes. The key step is the reduction of zinc oxide using a gas heated by an HTR.

At present there are two principal techniques involved in the zinc-making process: chemical reduction using coal, and electrolysis of zinc oxide. The first is carried out at temperatures of 1,200 – 1,400 °C and needs a correspondingly large supply of coke to provide these high temperatures. Zinc oxide might, however, conveniently be reduced using methane or hydrogen with an HTR as the source of process heat. In this case temperatures much below 1,000 °C are necessary—and these can be delivered by today's HTR technology. Natural gas or methane produced by coal gasification using HTR process heat can then be heated by the HTR to 800 °C and can be used for the reduction of zinc oxide. If this reduction has to be done with hydrogen, the latter might be produced by steam reforming of methane or water splitting, using process heat.

The zinc metal produced can either be sold or used in the aluminium-making process. Aluminium is at present produced by molten-salt electrolysis of alumina but high electrical energy requirements and high investment costs are disadvantages of this method. A new purely chemical reduction method, the so-called Toth process, seems to avoid these drawbacks. It is based on a four-step process in which aluminium metal is obtained from an ore containing alumina by way of aluminium chloride. Aluminium chloride is reduced with manganese metal yielding an aluminium–manganese alloy and manganese chloride, which is subsequently oxidised with air and finally reduced with coke at 1,750 °C.

Zinc might be used instead as reducing metal. In contrast to manganese oxide, the zinc oxide formed can be reduced by hydrogen or methane at temperatures far below 1,000 °C.

S. HUWYLER & W. SEIFRITZ

Würenlingen, Switzerland

Nitrogen fixation

SIR,—Does A. B. Lovins (May 1) really believe that those working on nitrogen fixation have not tried to imagine what would happen if they succeeded "beyond one's wildest dreams"?

What if one did develop universal nitrogen-fixing systems for plant life on this planet? The effect would be the same as if adequate conventional nitrogenous fertiliser were universally available: light, water, nutrients other than N (K, P, S, Co, Mo and so on) would become limiting, depending on the particular environments. Assuming all these deficiencies could be corrected artificially, CO_2 fixation would be the final limiting factor—as it is in advanced agricultural industry already.

The ecological and environmental effects would be just about the same as the use of nitrogenous fertiliser has entrained already, but the drain on the world's energy resources (for fertiliser production) would certainly be very much less. The pollution problem arising from run-off might also be lessened, though not eliminated—rotting legumes produce a run-off problem even today. In compensation, a few hundred million people on this planet would be better nourished and a few hundred thousand would be saved from death by starvation each year They would, of course, increase and multiply, so a global problem would be augmented and its solution postponed rather than solved. Yet some feel that there are better ways of tackling the population problem than by accepting starvation.

Ohta and evolution

SIR,—The paper by Ohta (November 29) on which my comments (April 3) have so displeased Nigel Calder (May 1), appeared under the rubric of "Review Article", which might lead the uninitiated (including perhaps Mr Calder) to expect a more or less scholarly summary of recent evidence and theories. What Ohta gave us, in fact, was a highly partisan presentation of the case for one side only on a controversial issue.

My remarks on statistics were perhaps open to misunderstanding; it was not intended to imply that statistical methods have no place in evolutionary studies—for example the statistical work of R. A. Fisher was a very important contribution to the theory of natural selection—but merely to point out that, in the macroscopic world at least, the appeal to chance is essentially an argument from ignorance, and should not be made until causal explanations have been clearly shown to fail

Mr Calder's reference to my remarks on scientific truths makes it clear that there are philosophical differences between us which would need more space for their discussion than this letter could afford. To quote a writer for whom Nigel Calder might have more respect than for the scriptures, William Blake wrote that "establishment of truth depends on destruction of falsehood continually"—in that spirit I was moved to express my criticism rather more forcefully than is usual in these columns.

Sunspots and the solar cycle

from T. G. Cowling

It is generally agreed that sunspots are surface phenomena, and that their darkness is due primarily to their possessing strong magnetic fields. It is also agreed that bipolar sunspot pairs arise when a bundle of the field lines of a subsurface azimuthal magnetic field has broken through the Sun's visible surface to form a magnetic arch above the surface. Nearly every other assertion made about sunspots has recently been challenged.

In recent years the origin of solar magnetic fields has customarily been explained in terms of dynamo theory. This theory, originating as a modification of a similar theory for the Earth, begins by assuming a poloidal field (one in meridian planes) which is twisted by non-uniform rotation to yield a much stronger toroidal (azimuthal) field. The dynamo has to be completed by a feedback mechanism converting toroidal field back into poloidal; the reconversion cannot be effected by axisymmetrical motions. Parker[1] in 1955 was the first to suggest a suitable mechanism. He showed that the reconversion could be effected by twisting (by Coriolis forces) the field embedded in material being carried upward because of thermal convection in the Sun's outer layers.

Parker's original discussion rested on general physical principles rather than on detailed mathematical analysis. But any defect in this respect has been amply rectified by later workers like Braganskii[2], Steenbeck and Krause[3], and Moffatt[4], who have also suggested other ways of securing feedback. In particular, the mean-field electrodynamics of Steenbeck and Krause, with their isolation of the so-called α-effect (currents parallel to the mean magnetic field) has supplied both a justification for Parker's ideas and a genuinely useful mathematical structure for use in dynamo theory. This structure has been used with conspicuous success in mathematical work on the Earth's dynamo.

In certain respects solar dynamo theory has been similarly successful. For example, as Parker originally surmised, it gives a field progressing towards the Sun's equator, and reversing periodically; this agrees with the observed progression of the sunspot belt towards the equator in any 11-year cycle, and the reversal of polarities in a bipolar spot pair in the next cycle. There is also some observational evidence of a reversing dipole field, at least in high latitudes. This field is, however, weak and uncertain; patches of both polarities are regularly present in each polar cap, and only in an average sense can one speak of the polarity of the cap as a whole. Surface observations provide little evidence of the regular dipole field required to initiate the dynamo cycle.

The observed field is represented more closely by a model suggested by Leighton[5] in 1964, and given mathematical form by him in 1969. This makes use of the tendency of the following spot of a pair to appear at a rather higher latitude than the leader spot, together with the spreading of fields over the Sun's surface by a random walk; this mechanism is employed as a substitute for Parker's feedback process depending on Coriolis forces. Leighton was able to get a 'butterfly' diagram in good agreement with observation for the progression of the sunspot zones towards the equator in any cycle; dynamo theory based on the α-effect makes new spots of a cycle appear at excessively high latitudes. Leighton also found a reversal of the polar (dipole) fields two or three years after the beginning of a new cycle, as observed, whereas α-effect dynamos tend to make the two nearly simultaneous.

Part of Leighton's success was due to his introduction of 'threshold' terms effectively limiting field generation to low latitudes, and ensuring that high-latitude fields arise only through the random walk. Apart from these threshold effects, Leighton's equations closely resemble those of an α-effect dynamo and, as Stix[6] recently showed, the α-effect dynamos can mimic Leighton's results if the law of non-uniform rotation is chosen such as to confine field generation to low latitudes. Leighton's discussion is in any case subject to the criticism that it relies over-heavily on purely surface observations, and gives little insight into the physics of the dynamo process at greater depths. Since the latitude effect invoked by Leighton is itself likely to arise from Coriolis forces, it is reasonable in discussing physical processes to confine attention to α-effect dynamos resembling that of Parker.

Piddington[7] has criticised such dynamos, on two main grounds. The first is that they create their new poloidal flux always at a higher level than the original flux, so that ultimately they should push the magnetic field out of the Sun. The second is that in order to get field reversal one needs not only to create new flux but to destroy unwanted old flux, and the electrical conductivity of solar material is too great to permit destruction in the relatively short times allowed. The reply of the dynamo theorists[8,6] has been that ohmic dissipation is supplemented by turbulent diffusion, which brings oppositely directed fields into close juxtaposition, so facilitating their mutual annihilation. Turbulent diffusion is also regarded as able to bring new magnetic flux down to the level of the old.

Piddington refuses to accept this reply as valid. He points out that surface observations do not support the concept of violently tangled fields, but show large patches of one polarity existing side by side with similar patches of the opposite polarity; small-scale dissipation, such as Stix[6] suggests on the basis of solar 'filigree' observations, can destroy small irregularities within the polarity patches but not destroy the patches themselves. He also argues that the concept of turbulent diffusion, though useful in discussing the transport of scalar quantities, is less satisfactory when discussing magnetic problems, where field lines have to be transported across field lines not in the same direction. Parker[8] has discussed mechanisms for speeding up the relinking of field lines in such transport. It is uncertain whether these mechanisms can work below the Sun's surface; Piddington asserts that in any case they cannot work fast enough until the field has grown so strong as to be able to choke the convective motions supposed to generate it.

Thus, though the dynamo equations certainly do give solutions that agree with the observed fields, Piddington asserts that these equations do not represent physical reality. Instead of the relatively diffuse fields of dynamo theory, he regards solar fields as composed of twisted 'ropes' (bundles of field lines) whose fields are strong enough to defy permanent distortion, and which are nearly indestructible. He quotes observational evidence in favour of this point of view. Away from sunspots, most of the surface magnetic flux is concentrated in small elements, with fields approaching 1,000*G*, situated at the junctions of supergranular convection cells. On dynamo theory such fields are supposed to be concentrated by the convection; he believes that they control it. More convincing evidence is provided by the facts that, when magnetic fields burst through the Sun's surface, they appear to do so as sets of individual ropes[9]; when a spot decays, it does so by peeling off ropes which are seen as magnetic 'knots' moving across a 'moat' surrounding the spot.[10]

Piddington envisages a sunspot magnetic field as a stranded cable of magnetic ropes. He regards twists of the ropes as essential, to avoid an exchange instability that would otherwise explode the field (however, this instability is not yet definitely established). He is unable to get a reversal of the Sun's field as a whole, and to this extent his ideas compare unsatisfactorily with those of dynamo theory. The best he can do is to create a reversing toroidal field from a nonreversing poloidal field limited to the deep interior, by a torsional oscillation similar to that originally considered by Walén[11] in 1948. As Stix[6] has emphasised, this idea meets with a number of difficulties, not the least being that it postulates a subsurface field unrelated to anything that we actually observe.

But the dynamo theory is subject to a similar objection. The polar field observed on the Sun is not the regular poloidal field posited by dynamo theory as its starting point; it seems rather to be an epiphenomenon, left over from sunspot fields. Also, as Altschuler *et al.* have shown[12], and as is confirmed by observations of the sector structure of interplanetary fields[13], the dominant large-scale field of the Sun rarely is that of an axial dipole; more often it is that of an equatorial dipole or quadrupole Thus, though the remarkable success of dynamo theory as a mathematical theory must be acknowledged, doubts must persist whether it explains the actual solar fields. One cannot but wish that one could look beyond the Sun's outermost atmosphere, and see what is going on at greater depths.

Drugs and nucleic acids

from Stephen Neidle

The nucleic acids DNA and RNA are undoubtedly among the best defined of all target molecules for the action of drugs, antibiotics and anti-bacterial agents. This has encouraged very many attempts over the past twenty years to define the molecular geometries of such drug–nucleic acid interactions, often with the ultimate hope of more effective and rational drug design.

It is nearly fifteen years since Lerman proposed his intercalation model for the interaction of aminoacridine mutagens, such as proflavine, with DNA; this model has survived the test of time rather well, at least in general terms. Lerman proposed that the planar drug molecule could slot (that is, intercalate) between the base pairs of DNA, with consequent unwinding of the double helix. He and numerous other workers have demonstrated by a variety of physical methods that many of the changes in DNA properties observed on binding can be directly attributed to intercalation. Unfortunately, although it has been established that helical unwinding does occur, the precise degree of unwinding has long been a point of uncertainty. Estimates have varied from 12° to 45° per drug insertion. Only very recently has the matter been clarified; the precise studies of Wang, using a buoyant density gradient caesium chloride titration method, have indicated that the correct value is 26° (*J. molec. Biol.*, **89**, 783; 1974). Although Wang's studies were on the DNA–ethidium system, there is good reason to believe that many other intercalating drugs untwist the helix by a similar amount.

Support for the intercalation model has now come from the crystallographic analyses of Sobell and his coworkers. They have capitalised on several recent findings that self-complementary dinucleoside monophosphates, such as adenylyl-(3′, 5′)-uridine, form Watson–Crick hydrogen-bonded dimers in the solid state, which can be considered to be RNA double-helical fragments. Sobell *et al.* have therefore used such fragments as nucleic acid models, and they have complexed them with the trypanosidal drug ethidium bromide, a well established intercalating agent. The preparation of complexes with 5-iodouridylyl-(3′, 5′)-adenosine and cytidylyl-(3′, 5′)-guanosine was briefly reported at a recent Royal Society Discussion Meeting, and Tsai, Jain and Sobell have now published an account of their X-ray structural studies on the former (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 628; 1975). The structural unit consists of a Watson–Crick base-paired dimer, to which is attached two ethidium ions. One of these is positioned between the base pairs of the now opened-up miniature double helix, and the other stacks externally on top of them. The intercalated ethidium has unwound the dinucleoside phosphate by about 12° compared with its uncomplexed conformation—this corresponds to unwinding angles of 26° for RNA, and 29° for DNA, assuming a direct correlation between model and polymer (nucleic acid) intercalation. As the authors do indeed point out, this assumption is unproven, in spite of the satisfying agreement of their result with Wang's.

There are in fact several features of this intercalative complex structure that may well belong merely to very small nucleic acid fragments, as well as to this particular analysis. Such a feature is the unexpected mixture of nucleotide sugar conformations, which could well have a significant effect on the unwinding angle. This structure forms an interesting contrast to that recently reported for another dinucleoside monophosphate–drug complex (Seeman, Day and Rich, *Nature*, **253**, 324; 1975), between the mutagen 9-aminoacridine and adenylyl-(3′, 5′)-uridine; this complex has an open, non-double-helical structure with drug molecules stacking on either side of, this time, Hoogsteen-type adenine–uracil hydrogen bonds in contrast to Watson–Crick base-paired adenylyl-(3′, 5′)-uridine itself. It is likely that the complex interplay of intramolecular forces which serves to stabilise double-helical nucleic acids is finely balanced for dinucleoside monophosphates. There seems to be no guarantee that these can preserve their 'mini nucleic acid' features when complexed with drugs. Probably only rather longer complementary oligonucleotides will satisfactorily reveal the molecular features of drug intercalation, especially subtle cooperativity and nearest-neighbour effects.

Prominent among many putative intercalating drugs is the plant alkaloid ellipticine, which has a planar ring structure capable of being inserted between base pairs. Ellipticine has received widespread attention on account of its high anti-leukaemia activity, which is believed to be related to its binding to nucleic acids (compare other anti-cancer drugs, such as actinomycin and daunomycin). Kohn, Waring and their co-workers have now established that this drug does indeed bind to DNA by an intercalative process (*Cancer Res.*, **35**, 71; 1975). The unwinding angle is less than that for ethidium, but very close to that for proflavine, another classical intercalating agent. Indeed ellipticine and proflavine have generally very similar binding behaviour, at least with calf thymus DNA, presumably because their molecular dimensions are so similar.

Le Pecq, Xuong, Gosse and Paoletti have used the intercalating properties of ellipticine in a systematic attempt to obtain highly active anti-cancer drugs by consideration of various ellipticine molecular modifications (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 5078; 1974). Their very simple reasoning was that, assuming DNA is the genuine cellular receptor for these drugs, a high degree of binding could correlate with high anti-tumour activity. DNA-binding constants and unwinding angles, and activity against L1210 mouse leukaemia, were determined for a series of derivatives; 9-hydroxyellipticine had the highest DNA affinity, and moreover had the strongest pharmacological activity. It seems plausible that the introduction of the hydroxy group has enhanced binding, by means of a hydrogen bond to a DNA phosphate group.

Of course, as Le Pecq *et al.* point out, strong binding to DNA does not by itself confer anti-tumour activity, as opposed to other biological activity— one of the derivatives tested by Le Pecq *et al.* had marked trypanocidal properties only. Many other molecular and indeed cellular properties are important. But one can certainly look forward to other successful applications of this straightforward approach to drug design.

A new theory of the Universe

from P. C. W. Davies

Fred Hoyle has long been known as a man with provocative and radical ideas about the nature of the Universe. During the 1950s and early 1960s he championed the famous steady-state theory of cosmology, in which the gross features of the Universe were assumed to remain unchanged for all eternity, a situation to be maintained by the continual creation of matter to fill the gaps left as the Universe expands.

This theory proved highly attractive philosophically, and was for a time very popular among cosmologists, but towards the end of the last decade, mounting observational evidence seemed to indicate that, rather than remaining unchanged, the Universe had a birth, growth and death, after the fashion of a biological organism. The 'big bang' theory is based on the assumption that the Universe was created about 15,000 million years ago in a hot, dense and violent expansion. A faint glow from this initial fireball is still detectable today, in the form of thermal radiation bathing the Universe at a feeble three degrees above absolute zero. This radiation is known in the trade as the microwave background.

Latterly, Professor Hoyle has accepted the concept of a hot big bang, but in a recent paper in *The Astrophysical Journal*, he describes a new and somewhat unusual perspective on this momentous event. In order to understand this departure, it is necessary to know something of the theoretical background to cosmology which Hoyle has developed with his co-worker Jayant Narlikar.

A perennial headache among physical scientists is to know which system of units to adopt for measurement of physical quantities. As it happens, nature supplies us with certain universal quantities against which it appears natural to measure everything else. Two such quantities are Planck's constant and the speed of light. Accepting these as our basic units of measurement, all other physical quantities may then be measured in terms of mass. For example, the mass of the electron is associated with a length of about 10^{-13} cm and a time interval of about 10^{-23} s.

Now it is generally accepted that the Universe is in a state of expansion, which is best visualised as a systematic and uniform growth in the scale of cosmic distances. To be specific, every day the observable Universe grows in scale by 10^{16} cm, or about 10^{29} electron mass units. This steady growth implies that in the past the Universe was shrunken, and simple versions of the big bang theory demand that 15,000 million years ago the shrinkage was complete, with the whole of the Universe which we at present observe squeezed up into a single point. This awesome event is generally known as a singularity, and is usually identified with the creation of the Universe. Certainly physical reasoning cannot be extended back through such a singularity.

The novel proposal made by Hoyle is to turn the cosmic scale change around, and regard the mass as the quantity which varies while the Universe remains static. Such a situation can be procured (mathematically) by changing the scale of measurement at different moments of time, something known to mathematicians as a conformal transformation. By thus transforming away the cosmological motion "The usual mysteries concerning the so-called origin of the Universe begin now to dissolve", according to Hoyle.

Lest the reader be suspicious about the creation of the Universe being removed at a (merely mathematical) stroke, even from the pen of so auspicious an individual as Professor Hoyle, something of the theoretical framework surrounding this new perspective should be mentioned. The use of conformal transformations to remodel the geometry of the Universe is often used for convenience of mathematical discussion. In this way the violent shrinkage of space near the big bang can be

A hundred years ago

The new Reptile House in the Jardin des Plantes, Paris, has sustained some heavy losses. A large turtle died from the shot it had received many months ago when captured in the Atlantic Ocean, and a large serpent from a wound inflicted by a rat. The rat having been offered as living food, resisted violently, and bit his adversary so deeply that he died a few days afterwards. The warders in the picturesque Reptile House will probably be more cautious in future in showing visitors the spectacle of Ophidians running after their food.

We are glad to say, however, that the above heavy loss will be to a considerable extent compensated, as the Jardin des Plantes will receive in a very few days a Boa more than eight yards in length, which has just arrived at Havre. We believe it takes a goat or a sheep to appease its appetite at one time.

from *Nature*, **12**, 54; May 20, 1875

'stretched out' again. The physical relevance of these transformations is usually limited, though, to considerations of systems without mass (for example, electromagnetism), simply because a non-zero mass changes under the transformation, and this is something not normally encompassed by conventional theories. But Hoyle appeals to a theory of mass and gravitation which he developed some years ago with Narlikar. In this theory, the mass of a particle is not a fixed, intrinsic attribute, but arises by an interaction between the particle and a 'mass field' which is in turn produced by all the other matter in the Universe, in a fashion often associated with the ideas of Mach. As a result, the mass field (and hence the particle mass) may vary from place to place, and time to time. By thus making variable mass a foundation stone of the theory, the use of conformal transformations fits quite naturally into the scheme. Not only massless systems, but all of physics, now become invariant under these transformations.

The utility of this extra flexibility is that the physicist is free to choose which conformal frame to work in. For example, by choosing the masses to be constant, the usual picture of an expanding Universe is obtained, and indeed the Hoyle–Narlikar theory then reduces to the conventional general theory of relativity. The singularity which occurs at the beginning of the big bang in this picture cannot be avoided in general relativity as a real physical catastrophe. But in the Hoyle–Narlikar theory this event merely signals a mathematical breakdown in the fixed mass frame, which may be neatly sidestepped by conformally transforming to the fixed Universe–varying mass frame.

The 'creation of the Universe' is then relegated simply to a moment when all masses happen to vanish, something which occurs quite naturally from time to time, according to Hoyle. The reason for this is that there exist both positive and negative sources of the mass field (reminiscent of positive and negative charges in electrodynamics), so that now and again an exact cancellation may occur.

Having thus argued that the big bang was not a creation event at all, Hoyle then goes on to ask the question: what happened before? In a brief discussion, some of the features which we now observe in the Universe and attribute to unknown properties of the big bang, are connected instead with processes occurring in an earlier phase. Some of the suggestions are not new, such as the energy to heat the fireball (visible now as the microwave background) originating from the accumulated starlight of an earlier phase. Others, such as the preservation of some residual stellar structure through the big bang/mass vanishing phase are quite unusual. The latter is used as an explanation of the deuterium to hydrogen ratio in the Universe, by speculating that synthesis of deuterium took place in regions of much lower density than average.

In summary, Hoyle has produced a picture of the cosmos which bears some similarity to the steady-state theory (no creation event) but still incorporates the essential features of the big bang fireball. The vital ingredient of the steady-state theory—the continual creation of matter to maintain constant entropy conditions—is not present, however. Consequently the new model suffers from the usual paradox of all infinite age cosmologies: why haven't irreversible processes generated unlimited entropy? Shouldn't the accumulated starlight in the fireball be arbitrarily hot from an infinity of previous phases? Nevertheless, many physicists may find this imaginative new picture a comforting circumvention of the unpleasantness of the initial singularity.

Disagreements over Troodos

from Peter J. Smith

DURING the past decade or so, almost all earth scientists with experience of the Troodos Massif of Cyprus have managed to convince themselves (and most others) that this ophiolite sequence is an upthrust fragment of ancient ocean floor and thus originally formed at an ocean ridge. It is a remarkable achievement, not least because the evidence, though strong and diverse, is almost entirely circumstantial; and the data required to remove all shadow of doubt remain to be found. In 1973, however, the consensus which had taken so long to build up was abruptly shattered by Miyashiro (*Earth planet. Sci. Lett.*, **19**, 218; 1973) who proposed instead that Troodos was created as a volcano in an island arc between Eurasia and Africa. The verbal reaction to this unexpected heresy was immediate, but the more temperate and reasoned criticisms have only now begun to appear in print.

Miyashiro based his case largely on comparisons between the geochemistry of Troodos rocks and that of recent ocean floor, on the one hand, and between Troodos geochemistry and island arc geochemistry on the other. In particular, he used SiO_2 contents and Fe/Mg ratios to show that the lower pillow lavas and the sheeted complex of Troodos contain a relatively high proportion of rocks with calc-alkalic affinities as well as others which follow the more expected tholeiitic trends. The significance of this discovery is that, if dredge samples are anything to go by, calc-alkaline igneous rocks of deep oceanic origin seem to be very rare. By contrast, island arc volcanism and calc-alkaline rocks are frequently observed in association. The implication, therefore, is that Troodos (and possibly other ophiolite sequences) is more likely to have been formed in an island arc environment than along an oceanic ridge.

The first serious criticism of this thesis now comes from Hynes (*Earth planet. Sci Lett.*, **25**, 213; 1975) who argues that rocks of the Troodos complex are so altered that bulk chemical analyses must be regarded as suspect, if not actually worthless, as indicators of origin. Indeed, the extensive alteration of the sheeted complex and the lower pillow lavas has been recorded by many workers since at least 1959 (see, for example, Wilson, *Geol. Surv. Dep. Cyprus Mem. 1*, 1959) and the abundance of secondary silica in Troodos rocks has been a frequent theme. On these grounds, therefore, any direct comparison between the chemistry of Troodos and that of unaltered rock from the ocean floor cannot be valid. To illustrate the dangers of placing too much reliance on chemical data, Hynes goes on to describe the Othris ophiolite suite in Greece which comprises rocks lithologically and petrographically similar to those of Troodos. The chemical characteristics are similar too, which would imply that Miyashiro's arguments are equally applicable. But in the Othris case there is stronger mineralogical, and especially regional geological, evidence in favour of a ridge origin against which the chemical data pale into relative insignificance.

In his reply to Hynes, Miyashiro (*Earth planet. Sci. Lett.*, **25**, 217; 1975) admits that some Troodos rocks have been subjected to secondary alteration but claims that these lie mainly in the upper pillow lava series which he ignored for that very reason. By contrast, rocks in other parts of the complex are "not so unusual in chemical composition". Many such rocks, for example, contain 70–80% anhydrous SiO_2; and if this had been brought about by the metasomatic introduction of silica into a basalt containing only 50% SiO_2, the proportion of material added from outside would have amounted to more than 100% of the original basalt. This, claims Miyashiro, is "not plausible". Primary silicic igneous rocks do therefore exist in Troodos and useful information may be obtained from their bulk chemical compositions.

In brief, this information is that about half of the volcanic rocks in the sheeted complex and lower pillow lavas of Troodos have $SiO_2>52.5\%$ and $FeO^*/MgO>2.0$ whereas most ocean ridge volcanics have lower values for these quantities. This is "decisive" evidence against an oceanic origin for Troodos but is consistent with formation in an island arc (although it is also consistent with a continental origin). Moreover, Miyashiro says that he "cannot understand" why the geological information quoted by Hynes supports the existence of accreting plate margins in the vicinity of Mesozoic Greece, arguing instead that this evidence is "so ambiguous" that it could be taken to support either view.

More generally, Miyashiro suggests that the world's ophiolite sequences are so diverse that some were probably created in island arcs, others at oceanic ridges and yet others in hot spots and stable continents. This point is well taken by Moores (*Earth planet. Sci. Lett.*, **25**, 223; 1975) who nevertheless feels that Miyashiro is wrong about the particular example of the Troodos Massif. Moores notes, for example, that much of Miyashiro's case is based on the premise that calc-alkalic rocks are rare in the ocean floor. But the fact is that most of the rocks obtained from the deep ocean floor have been dredge samples which are predominantly surficial and thus not representative of the oceanic crust as a whole. In this respect, Miyashiro has not been comparing like with like. When a crustal cross section has been sampled (for example, on faults in the Mid-Atlantic ridge and the Ninety East ridge), the rocks have been found to have compositions comparable to those of ophiolite sequences.

On the question of alteration, Moores has re-examined sections of the Troodos rocks analysed by Moores and Vine (*Trans. R. Soc.*, **A268**, 443; 1971) and finds that almost all of the rocks are indeed altered, most of them having abundant vesicles filled with zeolites or silica and many representing greenschist facies metamorphic assemblages. Thus in spite of claims to the contrary, Miyashiro has apparently been citing data influenced by metasomatic alteration. Primary SiO_2-rich igneous rocks do exist in ophiolites; but they account only for a very small proportion of the total volume and are significantly different from the genuine calc-alkilic rocks found in island arcs, especially insofar as they have much lower K/Na ratios. Moores thus concludes that bulk chemistry is not an adequate basis for differentiating between the products of ridges and island arcs and that recourse must be made instead to structural and stratigraphic arguments.

In a much longer reply to Moores, Miyashiro (*Earth planet. Sci. Lett.*, **25**, 227; 1975) attempts to refute his opponents' arguments in both general and specific terms,' on the basis both of "logic and evidence". On the question of ocean floor sampling, he claims (with evidence) that the Ninety East ridge is atypical of oceanic ridges and that there are no grounds for assuming that the mid-Atlantic ridge fault represents a particularly deep section of oceanic crust. At the same time, sampling is not as unrepresentative as is sometimes claimed because rocks formed at depth are exposed along median valley walls and in transverse fracture zones across oceanic ridges. On the question of alteration, he presents additional data to support the view that Troodos compositons cannot be attributed to weathering, metamorphism or metasomatism but arise in-

---

Anions and membranes

from a Correspondent

THE identification, isolation and partial characterisation of a human erythrocyte membrane protein essential for anion transport (Cabantchik and Rothstein, *J. Membrane Biol.*, **15**, 207–226 and 227–248; 1974; Ho and Guidotti, *J. biol. Chem*, **250**, 675–683; 1975) provides strong support for Gunn's hypothesis that the various anion exchanges observed in the red cell occur through the passive diffusion across the membrane of a common carrier–anion complex. It is of interest to compare this work with the recent work, particularly that of Narumi's group (*Biochim. biophys. Acta*, **311**, 80–89 and 90–97; 1973), on the mechanism of HCl secretion by gastric mucosal cells. As part of this mechanism internal bicarbonate is exchanged for external chloride, a situation analogous to that in the red cell, but in contrast to the red cell there is evidence of an active bicarbonate transporting system.

For many years it was thought that simple anions crossed the red cell membrane, diffusively, as free ions and that the differential permeability of the membrane to cations and anions was the result of fixed positive charges within the membrane. This theory was particularly attractive in the light of Bangham's work showing that the permeability of a simple lipid bilayer to different ions could be altered by changing the surface charge of the bilayer. A less attractive feature of the theory was the high activation energy of ion transfer.

This activation energy was closer to those usually associated with active ion transport. When it was shown that the rate of transport of several anions reached a saturation level as the ion concentration was increased the free ion diffusion theory had to be replaced by one involving a carrier ion complex Cabantchik and Rothstein showed that the carrier was a glycoprotein by treating red cells with a non-penetrating fluorescent marker (SITS). and demonstrating that sulphate permeability was inhibited when a relatively small population of sites on the external side of the membrane were labelled. They then isolated the label by proteolytic digestion and showed it to be attached to a glycoprotein of molecular weight roughly 9,500 Ho and Guidotti have also isolated a glycoprotein of similar size which is responsible for phosphate transport and identified it with Bretscher's component a. It is tempting to assume that these proteins are identical and are also responsible for the physiologically important chloride–bicarbonate exchange but this has yet to be shown.

As the mechanism of anion exchange in the red cell has become clearer that of the gastric mucosal cells has become more complex. The presence of a bicarbonate ATPase in gastric mucosa, and several other tissues where bicarbonate transport is important, has suggested the presence of a bicarbonate transporting mechanism analogous to the ATP-dependent cation pumps The demonstration by Namuri and Maki that carbonic anhydrase, which is necessary as a source of bicarbonate ions in gastric mucosal cells, is activated on phosphorylation by a cyclic AMP-dependent kinase would seem to complete the picture by linking the bicarbonate pump to hormones which control gastric secretion and which are thought to act by increasing the level of cyclic AMP in the acid-producing cells. The major problem in this picture is the localisation of the ATPase most of it is found in the mitochondrial and not the plasma membrane fraction (Soumarmon, Lewin, Cheret and Bonfils, *Biochim. biophys. Acta*, **339**, 403–414; 1974). But a bicarbonate pump in the mitochondrion would itself be of interest and the isolation of this ATPase as a Triton extract may indicate that a comparison between a passive and active carrier for the same ion will soon be possible.

stead from crystallisation differentiation. Moreover, he suggests that, by involving silica metasomation for Troodos, supporters of the ridge origin are contradicting themselves insofar as modern oceanic ridges show no signs of metasomatism.

In a final critical article, Gass *et al.* (*Earth planet. Sci. Lett.*, **25**, 236; 1975) point out, among other things, that in discussing the FeO*/MgO ratio Miyashiro has taken no account of the replacement of Mg-bearing mineral phases by carbonates and other non-magnesian pseudomorphs, and that the analyses quoted by Miyashiro were carried out before the precise boundary between the upper and lower pillow lavas was defined (so that many are in fact from the upper lavas). To these specific objections, however, Gass and his colleagues add what is perhaps the most telling general point of all, namely that in this whole argument there has been more than a tendency to ignore the wide variety of evidence available.

The fact is that few, if any, workers have claimed that an oceanic origin for Troodos has been proved. Instead, the case is based on an extremely wide range of evidence from many different branches of the earth sciences, with no single piece of evidence yet obtained being regarded as conclusive by itself. By concentrating public disagreement largely on the geochemical data, support for Troodos as ancient ocean floor has thus somehow been made to appear more equivocal than it really is. For the time being, the balance of argument remains with Miyashiro's opponents.

Rotating fluids

from a Correspondent

'Can the geomagnetic dynamo be powered by precession?' was one of the geophysically motivated questions raised at the recent Euromech meeting entitled "Non-linear processes in rotating fluids" held at University College, London between April 14 and 17.

THE sufficiency of precession as an alternative power source to convection in the Earth's core was discussed by Jacobs (University of Cambridge). Estimates of the power required to maintain the geomagntic dynamo against ohmic dissipation have been variously assessed as between 10^9 and 10^{12} W with the probable value between 10^{10} and 10^{11} W. According to Jacobs and his co-authors (Rochester, Smylie and Chong) the precessional power input to the core (at the expense of the obliquity) fails by at least two orders of magnitude to satisfy this requirement, and thus the possibility of a precession-driven dynamo is extremely remote. This contrasts with the views of Malkus (*Science*, **160**, 259; 1968) and, more recently, Stacey (*Geophys. J.*, **33**, 47; 1973) who have both argued in favour of precessional torques producing the driving mechanism for dynamo action. Jacobs attributed the disagreement not only to Malkus's failure to allow for electrical conductivity contrast at the core–mantle interface and Stacey's incorrect determination of the tilt-over angle, but also to the neglect by both authors of the dependence of the strength of the dissipative part of the core–mantle coupling on the diurnal frequency of the precession-induced core flow relative to the mantle. Loper (Florida State University and University of Newcastle upon Tyne) was equally pessimistic regarding the role of precession. His investigation of the transmission characteristics of the core's hydromagnetic boundary layers indicated again that precessional power is inadequate by at least 10^2.

In attempting to extend further the laboratory modelling of atmospheric flows in the rotating annulus, Leach (Meteorological Office) investigated the particular effects of topography and found that its presence significantly affected the well-known transitions between the different flow regimes and that it reduced the amplitude of the free baroclinic waves. The interplay between these free waves and those generated by the topography resulted in an increase in heat transfer, indicating that the free waves play a diminished part in the energetics of the system. A related study by Mason and Hide (Meteorological Office) into the effects of sloping end walls upon the transition from axisymmetric flow to baroclinic waves was illustrated by an interesting cine film. Various combinations of end-wall orientations were investigated and non-linear effects were identified by comparing the observed wave numbers with those predicted by appropriate linear theory.

The meeting also included contributions from other branches of fluid mechanics. Wimmer (University of Karslruhe) reported a very careful experimental investigation into the viscous flow between rotating concentric spheres (the outer sphere usually being stationary). Measurements of the friction torque were presented for a wide range of gap widths and Reynolds numbers. Photographs of the transitions from laminar stable flow to unstable flow to turbulent flow were shown and it was stated that, in addition to the well known Taylor–Görtler-type vortices, several new types of instability were discovered. One example in the wide gap case was a class of instability confined to the equator (the number of vortices being independent of Reynolds number) and having five different modes of instability for the same Reynolds number.

Several numerical investigations into atmospheric phenomena and related laboratory models were presented, including two papers by Hoskins (University of Reading) and Simmons (University of Reading) on non-linear properties of baroclinic waves and the formation of fronts, and the results of Quinet (Meteorological Institute, Brussels) on a numerical simulation of amplitude and tilted-trough vaccilation observed in the annulus experiments. Egger (University of Munich) reported the results of his numerical experiments on the cyclogenesis occurring in the lee of a long north–south mountain chain as this barrier is approached by a depression. By studying the time-development of the system it was claimed that a satisfactory mechanism for the cyclogenesis process could be obtained.

Space tribology

from a Correspondent

The first symposium in Europe, if not in the world, to be devoted to space tribology was organised by the European Space Research Organisation at its establishment at Frascati on April 9, 10 and 11.

THE papers varied from a very fundamental contribution by M. Barquins, R. Courtel and M. Maugis (Centre National de la Recherche Scientifique, Meudon) on the friction of Cu–Cu, Mo–Mo, Cu–Mo and Cu–Ni couples in ultra high vacuum to a paper by E. J. Robbins (European Space Tribology Laboratory, Risley) on the testing of the tribological performance of space mechanisms in a vacuum, in which the author presented a clear picture of the true environment in the satellite and considered the effect of water and other desorbed vapours on spacecraft mechanisms.

In general the emphasis was upon dry lubricated systems and a whole session was devoted to lead film lubrication of rolling element bearings, which is a largely European development, with now over 10^6 hours of vacuum operation to support it. The limitations of the performance of the film in air were clearly indicated in a paper by M. J. Todd (National Centre for Tribology, Risley) who reported tests showing rapid bearing failure at speeds beyond about 20 r.p.m.

Another session was devoted to the performance of slip rings in ultra high vacuum, mostly operating in the dry lubricated regime. The behaviour of slip rings under these conditions is surprisingly good, both from the point of view of low noise and low wear, and it is now possible to use them for mechanisms requiring lives of 6 to 7 years in space. The four papers in this session show that the European and US approaches are very similar, both using Ag.Cu.MoS_2 compact brushes on silver slip rings. A paper by W. Wilkens (DFVLR, Braunschweig-Flughaven) presented some new data on the performance of dry lubricated slip rings moving at very low speeds, such as are encountered on solar panel drives on communication satellites.

The only paper presenting work on gears in UHV came from E. Conde who reported some of the results of a very extensive programme at the CNES establishment in Toulouse. There seems to be no other work on the performance of gear pairs in UHV in progress in Europe.

One of the most important tribology problems for long life spacecraft is the provision of a bearing–lubricant system for momentum wheels. These units normally rotate at 3,000–4,000 r.p.m. and must perform reliably for 7 to 10 years in space. All momentum wheels flown to date are mounted on ball bearings with controlled minimum lubrication systems. W. Auer of Teldix, Heidelberg, presented a paper on the development of a European momentum wheel which is now flying in the Symphonie satellite and which embodies a lubricant store that progressively releases its oil to the bearings.

A unique and very interesting development in Europe is the application of grease lubricated hydrodynamic bearings to momentum wheels. Philips of Eindhoven have pioneered this work in the world and E. A. Muydermann and U. van der Wal presented two papers which discuss both the principle of the design and the present state of development. Nine bearing systems have each now completed more than 44,000 hours operation under various conditions of load and environment and the authors are now confident that all problems of shear instability and retention of the grease have been solved. The wheel has been chosen to fly in the ESRO Orbital Test Satellite now under construction

Also in the field of liquid lubrication was a paper by G. C. Friend, A. J. Grosiek, W. A. Ware and M Warwick introducing four new space lubricants developed by BP Research Centre Two of these are fine cut oils of very low vapour pressure, one a petroleum oil and the other a di-ester, which are available specially filtered in small quantities. The other two are greases based upon the oils but using oleophilic graphite to perform the dual role of boundary lubricant and thickener These lubricants are now undergoing life tests.

A very important paper by B. Baxter (British Aircraft Corporation, Stevenage) presented the results of a physical-chemical examination of the degradation of a grease which had run in a bearing for some 14,000 hours in vacuum. The author has developed at BAC a technique for examining the interaction of bearing and lubricant, which in this case was able to show that the 12 hydroxy-stearic acid in the grease-thickening agent is lost during running in low oxygen conditions. The technique is extremely valuable in gaining deeper insight into the reasons for bearing–lubricant system failure and the same author employed it very successfully in 1972 to explain the well known but poorly understood formation of 'brown sugar' in miniature bearings. The use of this technique in space tribology is very new but it can be expected to make significant contributions in the future.

The need for some harmonisation of the space tribology work in Europe was stressed by H. M. Briscoe, ESRO, in his closing address. ESRO is partly able to perform this task by acting as a clearing house for information and as adviser on future requirements, but he suggested that a small international advisory committee might be more effective at national level in preventing unnecessary duplication.

Crystallisation and chain extension in polymer solutions

from Paul Calvert

In recent years the study of morphology in crystalline synthetic polymers has reached an impasse. Twenty years ago the discovery that 10 nm, plate-like crystals could be grown from solution led to the development of the folded chain model, by Keller and others. Now, thousands of man-years of research and several hundredweight of publications later there is still little hard evidence as to whether the chains fold tightly or loosely and whether re-entry is adjacent to the point at which the chain leaves the crystal or whether it is at random. One way to try to gain more understanding is to look at the effect of aligning the chain before crystallisation. Mackley and Keller (*Phil. Trans. R. Soc.*, **278**, 29; 1975) describe such a study of molecular orientation and crystallisation in flowing polymer solutions.

In 1965 Pennings and Keil (*Kolloid Z.*, **205**, 160; 1965) described fibrous 'shish kebab' crystals, grown from stirred polymer solutions at high temperatures where unstirred solutions would not crystallise. These structures have been studied in detail by Pennings *et al.* (*Kolloid Z.*, **235**, 99; 1970; **237**, 336; 1970) by Krueger and Yeh (*J. macromol. Sci. (Phys)*, **B6**, 431; 1972) and by others. The shish kebab, of overall diameter about 1 μm and length up to several mm, apparently has a central core, the 'shish', about 20 nm diameter skewering lamellar crystals, the 'kebabs'. The shish and kebab are however molecularly connected, not distinct. It was found that turbulence was necessary for their formation, probably because this resulted in elongational as opposed to shear flow and so straightened the dissolved molecules.

Mackley and Keller give a detailed description of results obtained with an apparatus designed to produce pure extensional flow, first described with Frank (*Polymer*, **12**, 467; 1971). Two opposed jets of solution give extensional flow in the symmetry plane when both blow and on the common axis when both suck.

Calculations for dissolved polymer chains suggest that there should be a rapid increase in molecular extension at a critical flow strain rate, which is molecular weight dependent. Observations on the appearance of reversible birefringence in solutions above their crystallisation temperature support this and suggest that molecular alignment is almost complete. It should be noted though, that 95% alignment as measured by birefringence could still correspond to one sharp bend for every twenty chain units, so that the molecule is locally aligned yet compact in overall shape, like a pack of sausages. It would be helpful to have more information on molecular shape, such as a light scattering study might provide.

As the temperature is lowered fibrous crystallisation takes place in the high strain-rate regions of flow. The maximum temperature for crystallisation increases with strain rate, concentration and molecular weight as might be expected if the flow elongates the molecules, reduces their entropy and so increases the effective dissolution temperature. It should be possible to see crystallisation under flow temperatures where the crystals redissolve when flow stops.

The most remarkable morphological observation is that shish kebabs grown under extensional flow do not look any different from those grown from turbulent stirred solutions. Several models for the formation of these structures can be envisaged. Mackley and Keller seem to favour formation of an extended chain shish nucleus on which folded-chain lamellar kebabs subsequently grow. Alternatively the shish kebab could be a development of the stacks of polymer crystals formed from static solutions, where the stacks resemble either an open book or a spiral staircase. If the gaps between crystals were opened up these would look like shish kebabs. Nagasawa and co-workers (IUPAC Symposium on Macromolecules, Aberdeen, 1973) reported the formation of shish kebabs by deformation of single crystal stacks and suggest that the shish kebab structures produced from flowing solutions are also the product of the mechanical disruption of stacked single crystals by the fluid flow. This idea would explain the similarity of structures produced under different conditions, the amount of connecting material between kebabs and the general irregularities of shish kebabs. This question could be resolved by studies of how shish kebabs grow.

Thus this elegant work will add to our understanding of flow in polymer solutions and thermodynamic aspects of crystallisation but tells us little about the crysallisation process. Methods are still needed to study the molecular arrangement in these structures. Results on crystallisation of polymer melts in the same apparatus should be as interesting and more directly relevant to polymer processing methods such as fibre spinning. In this respect this simple, controllable crystallisation system could be very enlightening.

Halley lecturer produces new theory of comet origins

by John Gribbin

ON May 6 the 1975 Halley Lecture was presented in Oxford by W. H. McCrea, Professor Emeritus of the University of Sussex. McCrea took as the title of his discourse "The Solar System as a Space Probe", a far-ranging topic which suggests both an explanation of ice ages and a model for the origin of comets.

As McCrea pointed out, the advent of the space age has renewed interest in the study of the Solar System, but in many ways the Solar System itself is the best space probe of all, travelling at present towards a point in the constellation Hercules. The speed of the Solar System — 20 km s^{-1} relative to the rest frame of local stars; 140 km s^{-1} relative to the so-called 'high velocity' stars — may seem small compared with the speeds that are necessary to cross the Galaxy in a reasonable time, by human standards. But the great age of the Solar System, some 5 x 10^{9} years, suggests that even at these modest speeds the system has already orbited around the Galaxy 20 times. So there has been ample scope for samples to have been gathered from different regions of the Galaxy.

The most obvious features of spiral galaxies, like our own, are the spiral arms (made up of bright stars) and the associated dark lanes of gas and dust. Can the passages of the Solar System through these features have left traces for us to discover? McCrea suggests that they have. The spiral arms are thought to be a more or less permanent feature, with the dark lanes along their edges showing the formation of shock waves as clouds of gas run into the arms.

In our Galaxy, there are two main arms, and in round terms the time scales associated with the motion of the Solar System produce a passage across one arm every 100 Myr. It takes 10 Myr to cross each arm, and 1 Myr to cross the lane of shocked and compressed clouds at the edge of the arm. Now, the Sun is just entering the Orion arm, having recently passed through the compression lane which lies just inside that arm.

Following in illustrious footsteps (including those of H. Shapley in 1920 and 1949, F. Hoyle and R. Lyttleton in 1939) McCrea suggests that it is just such passages of the Solar System through the dark lanes which bring about ice ages. Details of this new variation on an old theme are shortly to be published in *Nature* (in our issue marking the 300th anniversary of the foundation of the Royal Greenwich Observatory).

But the astronomers among McCrea's audience really began to sit up and take notice when he moved on to discuss the problem of the existence of comets. These enigmatic objects, with masses in the range $10^{16}-10^{18}$ g, are the least massive members of the Solar System (except for small asteroids) but in many ways the most baffling. Have they always formed part of the Sun's family, or are they ephemeral visitors snatched from the depths of space? Most theorists seem to lean towards the former view; but McCrea has now come up with a model which might change that consensus.

The most popular concept of a comet (but not the only model) sees it as a 'dirty snowball' of water ice and silicates. As McCrea notes, this composition is much the same as the best available models of interstellar grains, which are now regarded as silicates covered by ice. So, if a ball of interstellar dust could be separated out from the gas, we would have something very much like the nucleus of a comet. The snag is that the presence of the gas will tend to keep the interstellar grains apart even in a situation where with no gas they would congregate under their mutual gravitational attractions.

McCrea gets round this by suggesting that dust can collapse independently of the gas if the mean free path of a gas molecule (relative to dust grain encounters) is longer than the minimum radius of a cloud of dust at the same density which would collapse if free from gas. Putting in the numbers, he comes up with a range of masses for the resulting aggregations, and these are just in the range of comet masses. For example, grains 0.25 μm across will form aggregates with mass about 1.6 x 10^{18}g. But to set the whole process off, the gas–dust mixture must be compressed to densities rather greater than the typical density of matter in intestellar space.

Once again, this is where the interaction of the moving gas with the spiral arms comes into the picture. 'Normal' clouds, says McCrea, have densities of about 0.1 – 10 molecules cm^{-3}. Dense clouds have about $10^{5}-10^{7}$ molecules cm^{-3} over regions one or more parsecs across, and the compression lanes must be at least as dense as the dense clouds. When a normal cloud hits a compression region, the first product is likely to be a dense cloud. At successive further compressions as the cloud continues its journey around the Galaxy and across spiral arms first cometary nuclei, then stellar and planetary condensations and even clusters of main sequence stars could be formed, depending on the starting density of a particular cloud. On that picture, the comets which now form part of the Solar System are a by-product of the recent passage through a compression lane, captured by the Sun en route. It may be that we are lucky to see any comets at all, and that for most of the long history of the Solar System there have been no comets bound to the Sun. Those we have at present will soon be dispersed, or broken up by repeated passage into the inner Solar System and past the Sun.

All this is dramatic enough. But the implications of the quite profound changes on Earth which occur as the Solar System moves through different regions of the Galaxy go still further. These "cosmic seasons", as Shapley dubbed them, could well have influenced the development of life, which (in the form we know it) may depend not just on the distance of a planet from its star, but also on the distance of the star from the galactic centre. McCrea terminated his lecture with the comment that the effect of all these astronomical influences on life "can be very complicated".

review article

Mutation selection and the natural history of cancer

John Cairns*

Survival of the rapidly renewing tissues of long-lived animals like man requires that they be protected against the natural selection of fitter variant cells (that is, the spontaneous appearance of cancer). This article discusses three possible protective mechanisms and shows how they could explain various features of the natural history of certain common cancers of man.

We are accustomed to thinking of the combination of natural variation and natural selection as a force for the good, that creates and maintains the fittest in a species and discards the unfit. This is the fundamental theorem of biology. But when we turn from the competition between the individuals of a species to the competition between the individual cells within a single animal, we see that natural selection has now become a liability. The dangerous mutations are now those that confer on a cell an increased survival advantage. We may therefore expect to find, especially in animals which undergo continual cell multiplication during their adult life, the evolution of mechanisms that protect the animal from being taken over by any "fitter" cells arising spontaneously during its lifetime—that is mechanisms for minimising the rate of production of variant cells and for preventing free competition between cells.

The cells of the surface epithelia that separate a typical mammal from its environment undergo continual turnover, and this turnover accounts for most of the cell division that occurs in the life of the animal. For example, a newborn rat contains some 3×10^9 cells and grows to a final value of about 6×10^{10} cells in old age; excluding any programmed cell death, the rat therefore represents a total of 6×10^{10} cell divisions. During its entire lifetime, however, the rat produces and discards about 10^{13} epithelial cells from its small intestine alone, and almost as many cells from various other epithelia[1]. Its risk of being overwhelmed by variants is, in principle at least, related to this total of 10^{13}. For man, who lives ten times as long and is one hundred times as large, there must be some 10^{16} cell divisions, and this number must somehow be reconciled with a spontaneous mutation rate of about 10^{-6} per gene per cell division[2–4]. Because most of the cell division is occurring in epithelia, that is where we may expect to find the protective mechanisms most highly developed.

Our interest in these protective mechanisms arises not least of all from the fact that they will determine how "fitter" variants are created by mutagenic agents and how such variants can be helped to supplant their normal neighbours (the process of carcinogenesis). Here we come to an added reason for concentrating on epithelia. Although most experimental cancer research, especially that using oncogenic viruses, deals with tumours of supporting tissues and blood-forming cells (the sarcomas and leukaemias), human cancer is predominately a disease of the various surface and glandular epithelia (Table 1).

This paper describes various ways in which the programme of cell renewal in epithelia may have evolved to minimise the risk from somatic mutation, and finally how certain features of natural carcinogenesis could be explained in terms of such a programme.

Lineages and the place of stem cells in programmes of cell renewal

The turnover that occurs in the self-renewing epithelia is the result of continual shedding of superficial cells balanced by continual multiplication of the deeper cells. In the simplest examples like skin, cell division is restricted to the deepest (basal) layer of cells. To keep the number of basal cells constant, one of the two daughter cells resulting from each cell division must on average remain in the basal layer and the other must escape and be discarded. Obviously there are several possible programmes of cell division that could produce this result: a regular programme of asymmetric division, where one of each pair of daughter cells is invariably exported (Fig. 1*a*); or a random choice of cells for export, the rule being simply that the available space for basal cells should be kept fully occupied; or lastly some more complex programme in which cells destined for export are allowed to undergo a certain number of divisions before they are exported from the basal layer (Fig. 1*b*). Some elegant experiments on the fate of pairs of daughter cells, arising in the rat oesophagus, suggested that the choice was random[6]. It now seems more likely, however, at least in skin[7,8] and small intestine[9], that a fairly rigid programme is operating of the kind shown in Fig. 1(*b*)—that is, most of the dividing cells produce descendants that are all ultimately exported.

An arrangement of this kind will decrease the rate of accumulation of spontaneous mutations and the risk from exposure to mutagens. The only mutations that accumulate during the life of an animal are of course those that arise in cells that themselves survive or contribute descendants that survive for the animal's lifetime—that is, the mutations must occur in the "immortal" stem cells (drawn as squares in Fig. 1). Any muta-

---

Buttonhole Lane, Mill Hill, London NW7, UK

tion that arises in a cell destined to be discarded will be lost (unless of course its effect is expressed quickly and serves to prevent the cell from being discarded).

The smaller the proportion of cells that are immortal stem cells, the lower the risk. In the different self-renewing systems of mammals the proportion probably ranges from one in ten (mouse skin)[8] to one in several thousand (bone marrow)[10]. But in most instances the number of immortal stem cells is not known. Note, however, that it may be much less than the number of cells capable of being promoted to immortality by force of circumstances (for example, that are capable of recolonising an epithelium or bone marrow depleted by X irradiation) or the number of cells that are still undifferentiated (the usual, but in this context less useful, meaning of the term "stem cell").

Stem cell division and the segregation of old and new DNA strands

Although the division of each immortal stem cell can produce two apparently indistinguishable daughter cells the fate of which may, in many systems, be determined simply by their position in space, it does not follow that the two daughters must be genetically equivalent and must therefore be equally likely to contain mutations.

Most spontaneous mutations probably arise as errors during DNA replication. Because DNA is duplicated semi-conservatively, these mutations are present initially in "heterozygote" molecules with one mutant strand and one normal strand. Unless such a heterozygote molecule is converted to homozygosity by one of the DNA repair mechanisms of the cell it will, on subsequent duplication, yield one normal daughter molecule and one molecule which is mutant in both strands (Fig. 2*a*). We see at once that stem cells would be protected against errors of duplication if it were so arranged that the immortal daughter cell always receives the DNA molecules which have the older of the two parental strands (that is, the rightmost molecules in Fig. 2*a*) and the mortal daughter always collects the molecules with the younger parental strand (that is, always collects the mistakes made in the previous generation). This rule would therefore maintain an "immortal strand" through successive generations.

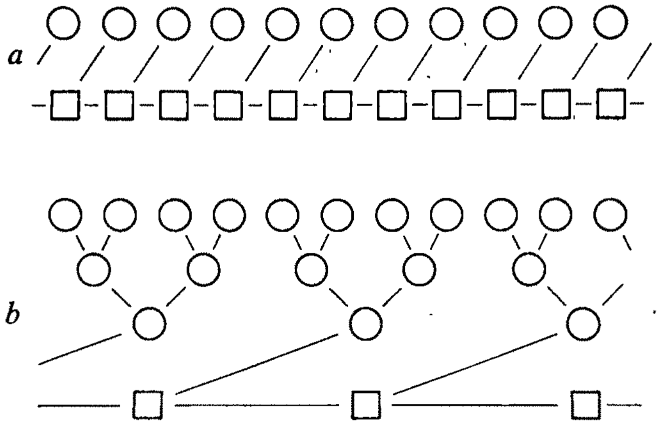

Fig. 1 Two possible programmes for the renewal of an epithelium by multiplication of the cells in the deepest (basal) layer, *a*, Renewal simply by regular, asymmetric division of stem cells; *b*, renewal by asymmetric division of the stem cells, plus some further division of the cells destined to be exported to the surface. The immortal stem cells are shown as squares and the mortal, differentiating cells as circles.

To operate such a rule, the immortal strands must all be marked in some way so that sister chromatids can be distinguished at the centromere, and all centromeres must behave in a coordinated fashion. Also, if the rule is to apply to all parts of the genome and not merely to the centromeric regions, the cell must ensure that sister chromatid exchanges are rare.

Table 1 Cancer incidence in Denmark, 1943–67

Type	Commonest sites	Total cases	%
Carcinomas			
External epithelia	Skin, large intestine, lung, stomach, cervix	168,591	56
Internal epithelia	Breast, prostate, ovary, bladder, pancreas	110,182	36
Sarcomas and leukaemias		23,801	8
	TOTAL*	302,574	100

These figures are drawn from three reports that together summarise the experience of the 4.5 million inhabitants of Denmark over a period of 25 years (ref. 5). They were chosen here because, unlike most national registries, the Danish Cancer Registry reports separately for each site the number of carcinomas arising in the epithelial (parenchymatous) cells and the number of sarcomas arising in the supporting cells.

* This total excludes about 10,000 cases in which the exact site of the primary cancer was not known.

In addition, if the fate of the two daughters of any immortal stem cell is determined by their position in space, the rule requires that each stem cell must enter mitosis with its duplicated chromosomes correctly aligned with respect to its surroundings. Up to a point this is certainly true. For example, in skin the plane of division of the basal cells is so arranged that both daughter cells initially lie side-by-side in the basal layer; further, there is some evidence that the successive mortal daughters of each stem cell lie alternately on one side and then on the other side of an unchanging plane of division[8]. In fact, such a pattern would fit nicely with the observation that when a given chromosome is followed through repeated rounds of duplication, in a cell forced to undergo endoreduplication by being grown in colchicine, each parental strand is found to have segregated first to one side of the plane of division and then to the other (Fig. 2*b*)[11].

Unlike the matter of stem cell lineages which is reasonably well understood, this speculation about the relationship between stem cell lineage and DNA lineage is completely unsubstantiated. In many instances, cells labelled in their DNA during one cycle have been shown to divide this label unequally among their grand-daughters[12], and there is one example of a cell with several chromosomes (the germinating spore of *Aspergillus*) which regularly segregates the DNA strands in these chromosomes as if they are parts of a single DNA duplex[13]. It remains to be shown, however, that epithelial stem cells behave in this way. The test, of course, is to see whether stem cells can be permanently labelled in their DNA at the time they are first formed (that is, can be shown to have a DNA strand that is immortal) or alternatively to see whether they retain the label only for one generation when labelled in an adult animal (that is, normally discard the newer of their parental DNA strands). Experiments of this kind are not yet completed.

Compartmentalisation and the natural selection of fitter variants

Having discussed two arrangements that would reduce the effective mutation rate in multicellular animals, we can now turn to a factor influencing the selective forces operating on mutant cells.

Most experimental cancers are formed only after repeated or prolonged exposure to a carcinogen. Similarly, most human cancers appear in old age, as if they usually arise as the end result of a lifetime of carcinogenesis. For this reason it is generally believed that several steps are required to convert a normal cell into an uncontrolled, invasive variant. The exact number of steps could be determined from the relationship between age and incidence provided that all steps occur at the same, unchanging rate[14,15]. If, however, the first step increases the survival of the altered cell so that this cell type steadily increases its number at the expense of normal cells, there will be a corresponding steady increase in the chance that somewhere there is a cell undergoing the next step, simply because with time there will be more and more first-step cells at risk[16,17]. So, whatever the number of restraints that must be overcome to convert a normal cell into a cancer cell, the risk that this occurs will be much increased if there are intermediate states with high survival advantage and if these variants are in fact able to displace their neighbours. We may therefore expect to find fast-multiplying tissues arranged in such a way that neighbouring stem cells (or sets of stem cells) are restricted to limited territories so that they cannot easily compete with each other.

The epithelium of the small intestine, which is the site of the most rapid cell turnover in the body, is an example of just such an arrangement. Cell multiplication is confined to indented regions of epithelium (the crypts) that project deep into the underlying mesodermal tissues. Between each neighbouring pair of crypts the epithelium forms a fold (the villus) that projects into the lumen of the gut. As a result of the continuous cell division in the crypts there is a continuous flow of cells from each crypt to the tips of the neighbouring villi, and from there the cells are shed into the gut[18]. Apparently each cohort of cells moves *en bloc* up the villus, propelled by the pressure of new cells being formed in the crypt. No matter how many immortal stem cells are normally present in each crypt (and the number is not known), any variant stem cell with high survival advantage should quickly exclude normal cells from its crypt. Unless this variant is, however, able to alter the whole structure of the epithelium (for example, by invading the surrounding mesoderm) the only way it can reach neighbouring crypts is by moving down the other sides of the villi, against the continual flow of normal cells arising in these crypts.

We see therefore that the arrangement of the intestinal epithelium into crypts and villi will tend to limit the expansion of any population of fitter variants that might otherwise form an ever-increasing target for further mutational steps. Other epithelia are no doubt partitioned in other ways. In each case the rules governing the territoriality of the proliferating cells will determine which kind of variants are the most successful.

Mutation selection and carcinogenesis

Restricting the number of stem cells, imposing a special pattern of segregation of DNA strands, and restraining the opportunities for competition between cells, are just three of the possible ways that may have been evolved in long-lived multicellular animals for diminishing the rate at which mutant cells accumulate. Of course, the rate would be further decreased if stem cells have unusually error-free forms of DNA synthesis and repair, perhaps in conjunction with a prolonged interval between successive divisions to allow ample time for any necessary repairs. The object of this article, however, is not to produce a list of all the factors that might affect mutation rate, but to show how the organisation of the self-renewing tissues of multicellular animals may often determine the sequence of events during carcinogenesis.

We have seen that the lineage of epithelial cells is so arranged that rapid renewal is normally achieved by rather few divisions of a special minority population, the immortal stem cells, which have a somewhat protected position deep in the epithelium and may, in addition, retain specially preserved DNA strands. The rate of accumulation of mutations in such a system will be proportional to the rate of division of the stem cells or perhaps, more specifically, to the rate at which they have to multiply to replace lost stem cells (that is, the rate at which new immortal strands have to be created). Anything that accelerates either of these processes could be carcinogenic. For example, cigarette smoking causes a thickening of the bronchial epithelium and obviously disrupts the ordered programme of cell renewal[19,20]. Judging from the relationship between incidence and age and duration of smoking[21], it seems that the smoker accumulates in each year about the same risk that 50 non-smokers accumulate collectively; alternatively, since incidence increases as the fourth power of time, it could be said that the smoker's bronchial epithelium goes through time at about 2.7 times the normal rate. It is tempting therefore to ascribe the increased risk of lung cancer simply to a 2.7-fold increase either in the rate of division of stem cells in the bronchial epithelium or in the rate at which

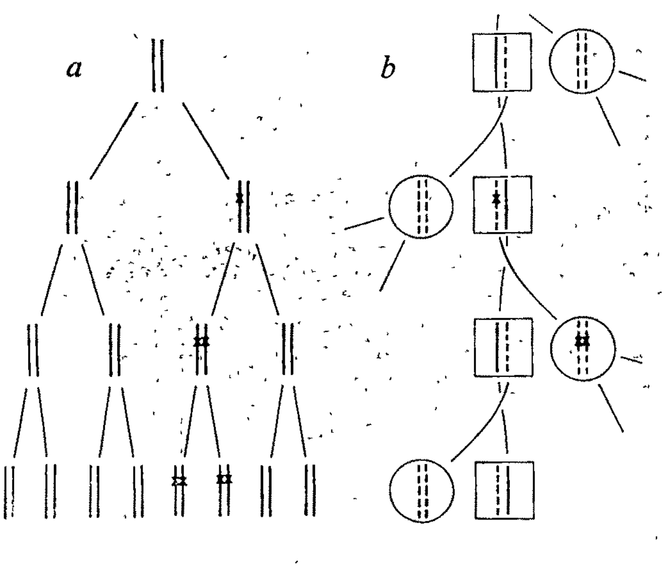

Fig. 2 The lineage of DNA undergoing semi-conservative replication. *a*, The segregation of a mutation, X, that arose as a copying error during duplication. *b*, Rearrangement of this lineage to fit the observation that parental strands apparently tend to segregate alternately to the right and left of the plan of division[11] and that, in one instance at least, the stem cells also move at division alternately to one side and then to the other[8]. The hypothesis therefore is that stem cells (☐) keep the same parental DNA strands through successive cycles.

these stem cells have to be replaced. This example shows that although it is customary to think of carcinogens as necessarily acting directly as mutagens, some could act indirectly simply by altering the programme of division of immortal stem cells.

Nevertheless there is no escaping the fact that the most powerful experimental carcinogens are intense mutagens. So we should now consider what general classes of mutation are likely to lead to cancer. In particular, because most forms of human cancer seem from their age-incidence to be the end-result of several consecutive, independent steps (mutations) we should be especially interested in those mutations that are likely to affect the subsequent rate of formation and selection of additional mutations. The previous example showed how a relatively slight change in the rate of stem cell division may have a great effect on cancer incidence. Obviously the same effect could be produced by an increase in the mutation rate per cells division, resulting from change in a gene with a product concerned with the duplication or repair of DNA. Unless such mutagenic mutations confer some survival advantage, however, they will remain confined to the stem cells in which they arise, and so only if they produce enormously increased mutation rate will they raise significantly the overall mutation rate; for a single cell to double the probability that an organ with 10^8 stem cells has experienced an event which increases as the fourth power of time, that cell would have to move through time (that is, collect mutations) at 100 times the normal rate. Probably more important, therefore, are mutations that affect the interactions of a cell with its neighbours. Any mutation that gives a stem cell the ability to move out of its compartment in an epithelium may cause it to form an expanding clone of stem cells, and because such a clone would be the site of an unusually rapid rate of formation of immortal strands it should show a much higher mutation rate than the rest of the epithelium; the first mutation would therefore be acting as a 'primer' for whatever succession of further alterations are needed to make a fully invasive cancer. The most carefully studied precursor states for any human cancer are the various precancerous abnormalities of the cervix, and they show exactly the properties we would expect of primer mutations. They are characterised by the appearance of extensive clones of cells[22,23] with deranged programmes of cell renewal[24,25]; further, although for obvious reasons the undisturbed natural history of these states is not well quantitated, it does seem that the successive levels of abnormality succeed one another with a rather high probability[26,27], as if the first level of abnormality has indeed raised the rate at which mutant cells accumulate.

If stem cells do preserve an immortal DNA strand through successive divisions, the only time when it should be easy to create a primer mutation (that is, immortalise an error) may be when these immortal strands are being synthesised—that is, when the epithelium is being created or is having to regenerate. It is therefore significant that carcinoma of the cervix usually arises immediately next to the boundary with the cervical canal, where the stratified epithelium of the cervix changes to the columnar epithelium of the canal[28]. The exact position of this boundary is known to fluctuate, and it is easy to imagine that the epithelium here is especially at risk because the local population of each kind of stem cell (stratified and columnar) has to rise and fall with each fluctuation.

Most epithelia probably establish their stem cells *in utero*[29], and so, if undisturbed, are unlikely to form primer mutations. One obvious exception, however, is mammary epithelium which proliferates after puberty with each ovarian cycle[30,31] and further proliferates during each successive pregnancy. In this special case a most interesting relationship is found between the extent of the proliferation that occurs during sexual maturity and the probability that cancer develops in old age[32]. The overall (lifetime) risk of cancer developing in childbearing women seems to be linearly related to the length of the interval that elapsed between puberty and the first full-term pregnancy, rising in value from 30% to about 130% of the value for women who never have children. So there are two unusual features to be accounted for: although the mammary epithelium proliferates at each successive pregnancy, it is only the first pregnancy that affects the risk of breast cancer; second, although the incidence of most cancers (this one included) rises as about the fourth or fifth power of age, the total lifetime risk of getting this cancer proves to be directly proportional to the length of one particular time interval. The explanation could be as follows. First, we suppose that the stem cells of breast epithelium increase in number at the time of puberty and then undergo a certain fluctuation in number with each ovarian cycle until the first pregnancy, whereupon the population builds up to a final level that is no longer influenced by the ovarian cycle or by additional pregnancies. Second, we suppose that the chance of a primer mutation occurring is simply proportional to the total number of times that immortal strands have had to be made in this epithelium (that is, the number of stem cell generations that have occurred)—much in the way that the frequency of mutants in a bacterial chemostat increases linearly with time[33]. Once pregnancy establishes the final unchanging population of stem cells, the epithelium becomes as protected against mutation as any other proliferating epithelium.

For obvious reasons, experimental carcinogenesis is usually studied in systems where brief exposure to a carcinogen produces a high incidence of cancer within a few weeks or months. It could be argued that such systems, using very strong carcinogens, are not suitable models for human cancer which typically arises at a slow rate after an incubation period of many years. Therefore this article, being on the natural history of cancer, has used examples of the common human cancers. The idea that special primer mutations are the first step in the formation of most cancers comes in large part, however, from certain reports of experimental carcinogenesis where the process could be divided into the separate stages of 'initiation' and 'promotion'[34,35].

I thank Drs Robert Kay, Guido Pontecorvo, Christopher Potten and many others for stimulating discussions and criticism.

article

Recent African rainfall patterns

Minoru Tanaka, Bryan C. Weare, Alfredo R. Navato & Reginald E. Newell

Department of Meteorology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

We present the results of a pilot study aimed at creating a more concrete basis for discussion of the variability in both space and time of rainfall in the Sahel.

FOR the purpose of this report we define the Sahel region as that running across the entire African continent between 10°N and 20°N. The area west of approximately 30°E is a fairly regular plain; to the east are the Nile River basin of Sudan and the mountains of Ethiopia.

The atmospheric circulation system that brings rain to this region is the ascending branch of the tropical Hadley cell, often called the Intertropical Convergence Zone (ITCZ), which moves north of the equator in the Northern Hemisphere summer. This system usually reaches its most northerly position in August so that this is the wettest month over the entire broad region of the Sahel[1]. We have concentrated on August for the African region for the years of good climatic records, 1941–73.

The data for this study were derived from the published monthly records[2] and a magnetic tape of global surface data before 1971 furnished by the National Center for Atmospheric Research. Meteorological agencies of the United Republic of Cameroon, Ethiopia, the Republic of Ghana and the Republic of Mali provided supplementary data.

Figure 1 illustrates the average rainfall patterns for August for the African region for the periods 1941–50 and 1951–60. The stations which usually report are indicated by dots. A similar map for the 10-year period 1961–70 has not been produced at this time because of important gaps in reporting. Several features of these maps are important. The Sahel region had about 10% more rainfall in 1951–60 than in the earlier decade; the centre of the maximum precipitation was approximately 1° farther south in the earlier decade than in the latter; the August rainfall belt across approximately 15°N has two distinct regions, one covering the large plains in western and central Africa and the other in the proximity of the Nile basin and Ethiopian highlands; and there are two areas of orographic rainfall suggested by the small areas averaging more than 600 mm of precipitation for the month.

In Fig. 2 we show analyses of the August precipitation data for 1964, 1968 and 1972. That for 1964 shows a month of relatively heavy rainfall over the Sahel. The pattern is quite similar to those of 1951–60; 1968, on the other hand, is the year in which the belt of maximum precipitation underwent the smallest northward displacement in the 33 yr of adequate record, to only about 7.5°N, compared with the average of about 12.5°N for 1951–60. Nevertheless, August 1968 was not the driest recorded in the Sahel, which suggests that the meridional gradient of precipitation was flatter in this month than in other drier months. Another indication of the uniqueness of this month is the region of heavy, flooding rainfall along the normally dry southern coast between 10°W and 0° longitude[3].

The years 1972 and 1973 were those of lowest precipitation in 1941–73 in the Sahel. This is clearly indicated by the break in zonality of the 200 mm isohyets along 15°N in the map of August 1972.

Figure 3 illustrates a relatively crude attempt to show meridional 'cross sections' of the rainfall pattern across the Sahel, derived from a series of eight stations along approximately 0° longitude, for August of 1964, 1968 and 1972 and the long term mean. The figure suggests that August 1964 was indeed wetter than the mean in the Sahel region but drier in the region between 5°N and 10°N. The curve for August 1968 further illustrates the relatively limited northward migration of the zone of maximum precipitation inferred from Fig. 2. August 1972 seems to have had decreased rainfall for the whole region illustrated, with a centre of maximum precipitation slightly south of that of the mean.

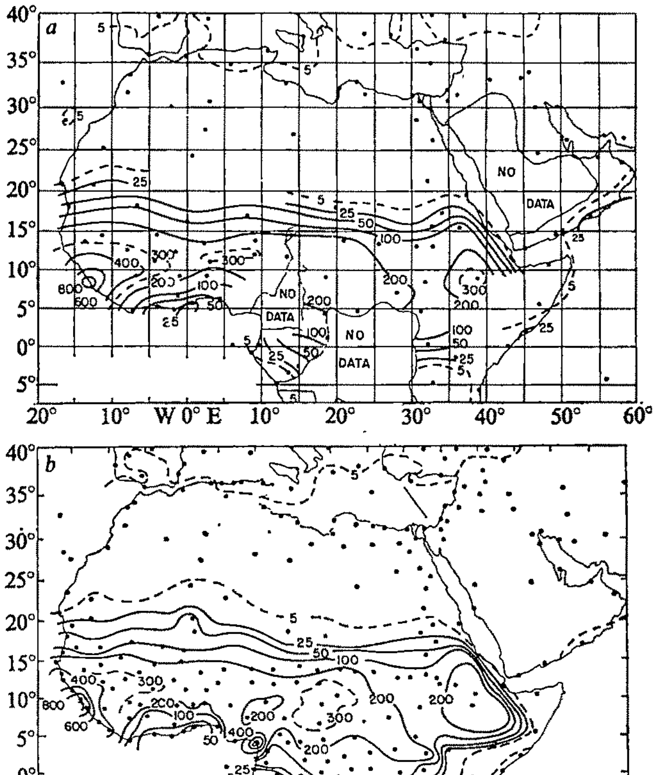

Fig. 1 Analyses of average August precipitation data (mm) for 1941–50 (*a*) and 1951–60 (*b*) for the African region. Dots locate positions of stations which usually report in the respective decade.

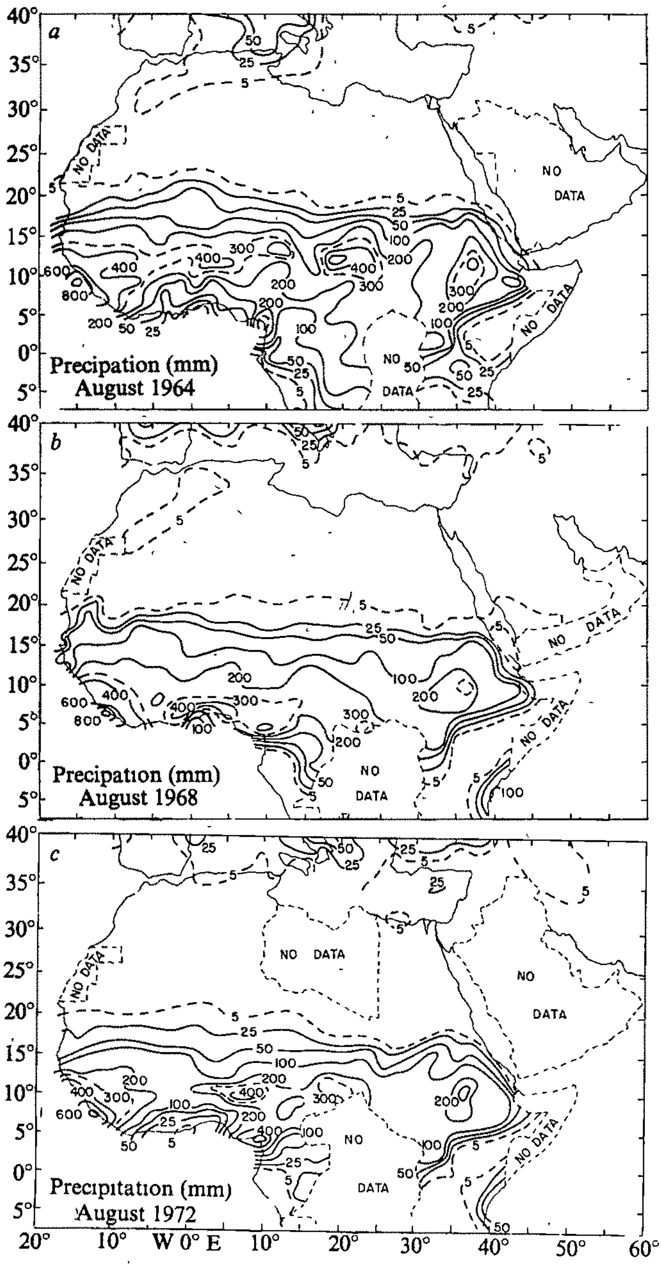
Figure 4 portrays five possible measures of the 'intensity of drought' for the Sahel. The lower two curves show the arithmetic mean August and annual precipitation of eight stations along 14°N. The stations were picked because of their proximity to the chosen latitude, their relatively equal amounts of August and annual rainfall, and their nearly continuous records since 1941. El Fasher was chosen as the most easterly station considered because data from sites near the Nile basin and Ethiopian mountains tend to obscure the clear trends in the region west of about 30 °E (Figs 1 and 2). These curves show that the patterns in time of August and annual data are very similar. The wettest five-year period was that from 1950 to 1954, which had about 120% of the long term annual mean. The driest was 1968–72, with about 80% of that mean.

The middle curve of Fig. 4 shows a line drawing of the average August precipitation along 15°N between 10°W and 25°E obtained from the entire set of analysed maps. The curve directly above indicates the average latitude of the 100 mm isohyet in the Sahel between 10°W and 25°E as read from the same maps. The lines for the 1951–60 means are the result of similar readings of the 1951–60 map (Fig. 1). The top curve of Fig. 4 indicates the approximate latitude of the centre of maximum rainfall (centre of gravity) near the prime meridian as interpolated from the August analysed maps. Figure 4 clearly shows that 1968–73 was the driest six-year spell of the period covered by good records.

Fig. 2 Analyses of August precipitation data for 1964 (*a*), 1968 (*b*), and 1972 (*c*) for the African region.



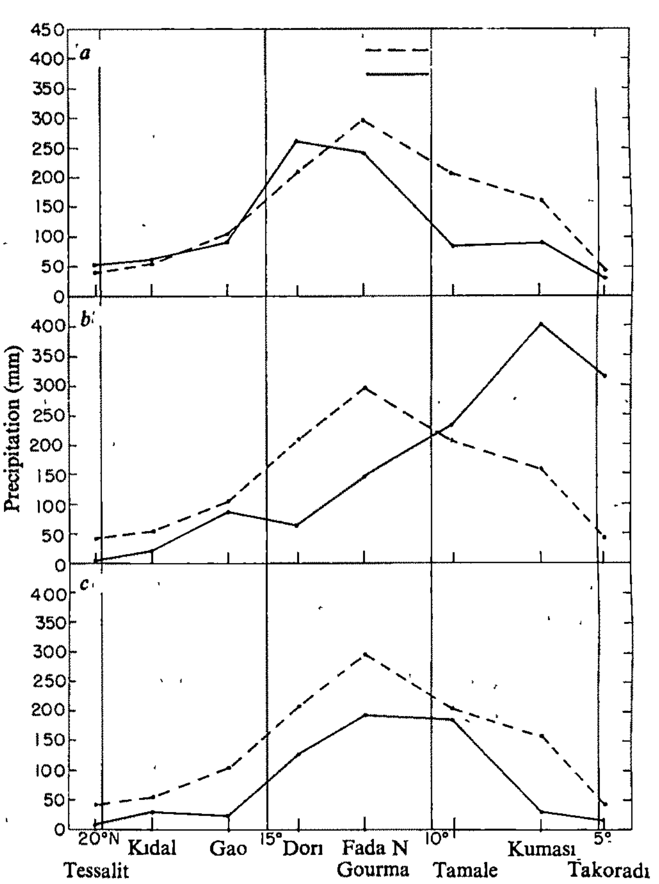


Fig. 3 Plots of August precipitation data for the eight stations listed, which are approximately along the prime meridian, for 1964 (*a*), 1968 (*b*), and 1972 (*c*), together with the long term mean. Station positions are: Tessalit, 20°12′N, 0°59′E; Kidal, 18°26′N, 1°32′E; Gao, 16°16′N, 0°37′W; Dori, 14°2′N, 0°3′E; Fada N Gourma, 12°04′N, 0°21′E; Tamale, 9°25′N, 0°53′W; Kumasi, 6°43′N, 1°37′W; Takoradi, 4°53′N, 1°46′W. — — — —, Climatology; —, precipitation.

The slight discrepancies between the five curves further indicate the difficulty in determining a single quantitative measure of regional precipitation patterns.

The 12-month running means of the entire record of several stations having data for the years before 1941 (including Accra, 5°33′N, 0°12′W; El Fasher, 13°38′N, 25°20′E; Kano, 12°3′N, 8°32′E; Khartoum, 15°36′N, 32°33′E; Lungi, 8°37′N, 13°12′W) were computed. Taken as a whole, these tend to confirm Jenkinson's[4] conclusion that there was a severe drought for a three-year period centred on 1913 and a less severe one around 1926. In addition September volume flow measurements[5] of the Niger River at Kayes indicate that the flow in 1913 was about 28% of the mean for 1903–68, the lowest reported up to 1968. The flow in 1926 was 59% of the mean. The running means were also compared to the curves of Fig. 4. Unfortunately, each station failed badly to correlate with the curves in at least one distinct year with the exception of Kano, which has an unfortunate lack of data in the critical period after 1966. This finding, combined with the fact that there are only a few poorly distributed stations in the Sahel for the earlier period, seems to preclude a comparison of the severity of earlier droughts with the most recent for the broad Sahelian region.

Spatially, both the position of maximum rainfall and the northward gradient from that position are necessary to specify the precipitation pattern over the Sahel. In addition, the

Table 1 Climatic data from analysed global maps

	1961	1962	1963	1964	1965	1966	1967	1968	1969	1970	1971	1972	1973

700-mbar height over the Atlantic at 25°N in August	3,209	3,200	3,210	3,210	3,215	3,210	3,220	3,210	3,210	3,215	3,210	3,220	3,210
Latitude of 700-mbar high over the Sahara in August	30°N	32°N	30°N	29°N	30°N	27°N	30°N	27°N	25°N	30°N	30°N	25°N	30°N
Latitude of 700-mbar high over the Atlantic in August	32°N	33°N	33°N	33°N	30°N	32°N	32°N	27°N	32°N	32°N	33°N	32°N	32°N

patterns of precipitation for the large area of plain west of about 25°E are only related to those east of that longitude in a complex fashion. This is perhaps not surprising if one considers the orography of the eastern region and the difference in average wind patterns of that region compared to those of the central and western Sahel[1]. So Khartoum and other Sudan stations are not representative of the large scale trends and are therefore probably of little value in estimating trends before 1941. Finally, the 1968–73 period was indeed the most distinctive since 1941, although the period around 1913 may be comparable. Preliminary reports suggest that Sahelian rainfall was near normal in 1974. The eight-station average for August 1974 is indicated in Fig. 4.

Winstanley[6] has suggested that Sahelian rainfall is negatively correlated with the southernmost position of the troughs in the mid-tropospheric circumpolar westerlies as inferred from winter-season 500-mbar analyses at 40°N between 110°W and 70°E. His results have been interpreted as a migration of the Sahara southwards during 1968–73. We have prepared 700-mbar height analyses for January and August for the years 1961–73. From these, values were read at each 10° meridian around 50 °N. The averages of these heights are given in Table 1. Given the relative randomness of the results for January and the large standard deviations within a latitude circle (about 95 geopotential metres, gpm) there does not seem to be any trend in these heights which could be correlated with Sahel rainfall trends (see also ref. 7).

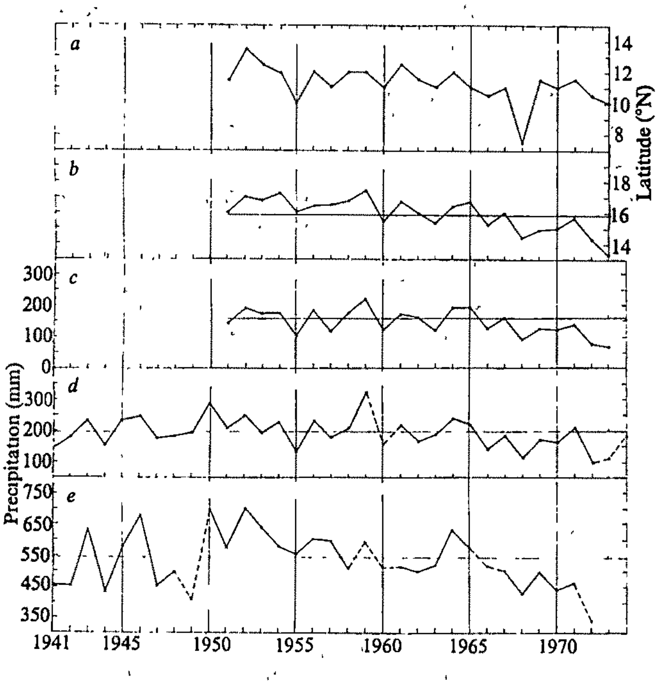

Fig. 4 Plots of five measures of rainfall for the Sahel region from 1941 or 1951 to 1973. The data of the upper three curves were read from analysed August precipitation maps. The bottom two curves indicate the averages of the station reports at: Tambaconda, 13°46′N, 13°41′W; Kayes, 14°26′N, 11°26′W; Mopti Severe, 14°31′N, 4°6′W; Gao, 16°16′N, 0°37′E; Niamy, 13°39′N, 2°10′E; Zinder, 13°48′N, 9°0′E; Abecher, 13°51′N, 20°51′E; El Fasher, 13°38′N, 25°20′E. Dashed lines indicate one station report has been objectively interpolated using the long term means and that year's actual reportings for the other seven stations. *a*, Latitude of centre of gravity, 5°W–5°E; *b*, August latitude of 100 mm precipitation, 10°W–25°E (solid line, 1951–60 mean); *c*, August precipitation along 15°N, 10°W–25°E (solid line, 1951–60 mean); *d*, eight-station mean August precipitation (solid line, 1941–70 mean); *e*, eight-station mean annual precipitation (solid line, 1941–70 mean).

In Table 1 we also present estimates of the latitude of the August subtropical high and the 700-mbar height at 25 °N in the regions of the Sahara and the central Atlantic. Neither the Atlantic data nor the August global averages of 700 mbar height at 50 °N (standard deviations about 30 gpm) show a clear trend. The Atlantic estimates would not support Bryson's[8] contention that Sahelian rainfall patterns can be inferred from the position of the subtropical high over the Atlantic. Namias[9], on the other hand, has reported evidence of negative correlations between the geopotential over northeast Europe and the rainfall for three stations in the Sahel for the summer season. Both the latitude of the subtropical high and its height at 25° N north of the Sahel suggest a southerly migration of that high by about 2° of latitude from 1961–65 to 1969–73. The cumulative regional and global geopotential evidence suggests a slight change in the morphology of the subtropical high pressure belt and the trough of the mid-latitude westerlies during 1968–73, but does not seem to be consistent with a suggestion of a global expansion southward of either.

Available German Weather Service global surface temperature departure maps[10] have been supplemented by our own plots of the station data to provide analyses for January, July and August of 1961–73. The August temperatures of the Sahel were warmer during 1968–73 than the long term mean, with departures exceeding 2 °C in 1968 and 1972. Satellite measurements suggest that this can be attributed, in part, to increased solar heating at the surface due to the decrease in cloudiness and consequent change in overall albedo during this relatively dry epoch. In 1969, for example, the total albedo over the Sahel was about 35% in July and 26% in the following dry month of October[11].

We thank the United States National Science Foundation for support.

letters to nature

Magnetic field of Mercury confirmed

On March 16, 1975, the US spacecraft Mariner 10 underwent its third and final encounter with Mercury. This unique and fortuitous event occurred because the heliocentric orbital period of Mariner 10 was 176 d, exactly twice that of the orbital period of Mercury. The principal objective of the third fly-by was to confirm or reject the suggestion from the first fly-by on March 29, 1974 that Mercury may possess a modest intrinsic magnetic field sufficient to deflect the solar wind flow[1-2]. The quantitative analysis[3] of the Mercury I data yielded an estimate of the planetary magnetic dipole moment equal to 5.1×10^{22} gauss cm^3 and oriented 7° from the orbit normal. The spacecraft had not been functioning properly since Mercury I because of various technical failures, but the spacecraft engineering team at the NASA Jet Propulsion Laboratory (JPL) managed to achieve the desired objective at Mercury III of a very close dark-side pass. Here we present preliminary results from the NASA Goddard Space Flight Center magnetometer instrumentation on Mariner 10.

The fly-by trajectory is shown in planet centred solar ecliptic coordinates in Fig. 1. This is a preliminary trajectory and will eventually be updated by means of tracking observations made after the encounter. The nominal 'miss distance' at closest approach was approximately 323 ± 8 km. For comparison, also shown in Fig. 1 is the trajectory at Mercury I encounter, for which the miss distance at closest approach was 704 km. In Fig. 1*b*, showing the view from the Sun, the much higher latitude of the spacecraft pass during Mercury III is well illustrated. This closer and more poleward targeting was chosen so as to yield magnetic field measurements which would provide unequivocal evidence about the nature of Mercury's magnetic field. The Mercury I results were consistent with a reduced-scale model of the interaction of the solar wind with the terrestrial magnetic field, in which the planetary field is compressed by the solar-wind flow (itself deflected around the planet) and a detached bow shock wave forms. As a result, the field is then confined to a region close to the planet on the Sunward side and extended to form a magnetic tail on the night side.

Based on the observations and analysis at Mercury I and assuming similar conditions of solar-wind momentum flux at Mercury III, predictions were made of the locations of the characteristic bow shock and magnetopause boundaries (Fig. 1*a*). Since the rotation period of the planet is uniquely coupled to its orbital period, in the ratio 2:3, the 'phase' of the planet relative to the planet–Sun line at successive encounters was identical.

The observed positions of the bow shock and magnetopause during Mercury III are also illustrated in Fig. 1. They show excellent agreement with the model boundaries, which used a scale magnetic moment of Mercury equal to 7×10^{-4} that of the Earth's dipole moment. In the case of the solar-wind flux impinging normal to a dipole field, a theoretical study[4] has yielded the relationship

$$R_{mp}/R_p = 1.07\,[B_0^2/4\pi mnV^2]^{1/6}$$

where R_{mp}/R_p is the normalised radius of the stagnation point distance of the magnetopause, B_0 the equatorial dipole field intensity, and mnV^2 the solar-wind momentum flux (where n is the number density, m the mass of the proton and V the velocity of the solar wind). The distance to the magnetopause, as measured by R_{mp}, thus depends weakly on the solar-wind momentum flux and, therefore even if variations of ±60% in the solar-wind flux occur, they would alter the position of the characteristic bow shock and magnetopause boundaries by only ±10%.

The magnetic field measurements were accomplished with a dual magnetometer system[5] which sampled the vector magnetic field 25 times a second, with a precision of $\pm 0.125\,\gamma$ for each orthogonal component. These data are to be considered preliminary in that they are accurate to ± 1–2γ or ±1%, whichever is the larger, because they are derived from quick-look data provided in near real time by the JPL. Six-second averages of the observed magnetic field throughout the encounter period are

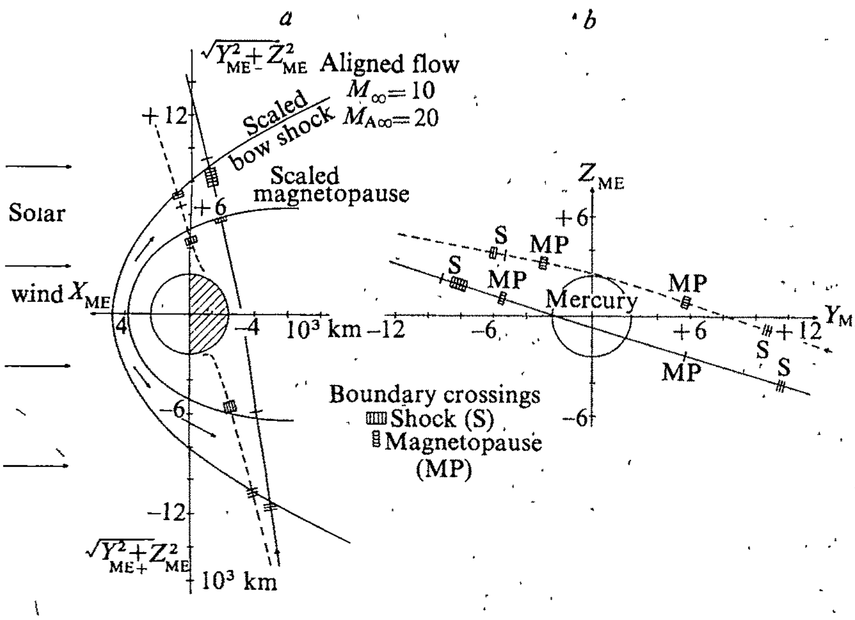

Fig. 1 Mariner 10 spacecraft trajectory in Mercury-centred solar ecliptic coordinates. *a*, Trajectory plotted as distance, X_{ME}, from the dawn–dusk terminator of the planet against distance from planet–Sun line, $(Y_{ME}^2+Z_{ME}^2)^{1/12}$. shown in Fig. 2. The occurrence of the well developed bow shock and magnetopause boundaries are indicated and readily identified by a magnitude and/or directional change as well as in the Pythagorean mean fluctuation characteristic, *RMS*. The maximum magnitude of the field is 400 γ, four times larger than that observed at Mercury I encounter and 20 times larger than the interplanetary field, which is close to 20 γ. This large value precludes any reasonable possibility that the magnetic barrier to solar-wind flow is associated with a complex induction process occurring at the planet. The direction of the magnetic field, as measured by latitude θ and longitude φ, is primarily towards the Sun (and planet), with gradual changes along the trajectory within the magnetosphere boundaries. This orientation is opposite to that observed at Mercury I but is consistent with the model of a Mercurian magnetosphere (Y.C.W. and N.F.N., unpublished) in which the planetary field is represented by a centred dipole normal to the flow of the solar wind and which is then highly distorted by magnetopause currents.

Table 1 Comparison of planetary dipole moments obtained by spherical harmonic analysis of magnetic field data

	Mercury I March 29, 1975	Mercury III March 16, 1975
Dipole moment (gauss cm^3)	5.1×10^{22} ($350\gamma\ R_m{}^3$)	$4.8 (\pm 0.5) \times 10^{22}$ ($330 \pm 30\gamma\ R_m{}^3$)
Latitude (ME coordinates)	−80°	−76° ± 5°
Longitude (ME coordinates)	285°	90 ± 30°
Root mean square residual	0.9 γ	7 γ
Comment	Quiet data only	Preliminary but entire data set

A preliminary spherical harmonic analysis of the data within the magnetosphere has been carried out using the available trajectory. The analysis assumes a centred planetary dipole field (harmonic order $N = 1$) as well as external field sources described by harmonic terms up to order $N = 2$. The preliminary least-squares fit yields a residual of 7γ with the deduced parameters for the planetary dipole listed in Table 1.

These are compared with those values derived from Mercury I and are seen to be in remarkably good agreement, considering the preliminary nature of these results. The magnitude of the dipole moment is the same within 10% and its direction only 24° from that derived earlier. The uncertainty associated with the present analysis means that we cannot attribute any significance to these small differences.

In summary, the observations at the third encounter with Mercury by the NASA GSFC magnetic field experiment have confirmed the earlier tentative conclusion that Mercury has a modest, intrinsic magnetic field, the origin of which is at present uncertain. It may be associated with remanent magnetisation of parts of the planet (material at present below its Curie point) or it may be caused by an active dynamo in the presumably large iron–nickel core. It is, however, difficult to construct a plausible sequence of events leading to the model in which the Mercurian magnetic field is explained in terms of remanent magnetisation, so we conclude tentatively that these observations require the existence of an active dynamo mechanism.

We thank Dr James Dunne, JPL Project Scientist on Mariner 10, and the JPL spacecraft team for their outstanding effort in achieving the third encounter. We also appreciate the special efforts of D. H. Howell, F. W. Ottens and R. F. Thompson of the NASA GSFC for their special efforts and prompt analysis of these data.

Preliminary interpretation of plasma electron observations at the third encounter of Mariner 10 with Mercury

OBSERVATIONS of electrons with energies between 13.4 and 690 eV made at the first encounter of Mariner 10 with Mercury (Mercury I) unexpectedly showed[1] the presence of a strong bow shock wave, enclosing a magnetosheath and magnetosphere with boundaries the positions of which could be explained by assuming Mercury to possess an appreciable magnetic moment, in agreement with, and complementary to, the observations made by the magnetometer carried by the spacecraft[2]. Inside these boundaries were found distinct distributions of magnetospheric particles.

A second encounter took place on September 21, 1974, but the spacecraft passed the planet on the Sunward side at too great a distance to permit observations inside the planet's bow shock. The third, and last, encounter (Mercury III) took place on March 16, 1975 at which time the spacecraft passed within 330 km of the surface of the planet, along the trajectory shown in Fig. 1. The primary purpose of this close polar approach was to determine whether the magnetic moment of the planet was intrinsic and to enable further observations to be made inside the magnetosheath and magnetosphere.

The results presented here are from an electron spectrometer mounted on a scan platform. It accepts electrons from the anti-solar direction in the energy range 13.4–690 eV in 15 logarithmically spaced channels of width $\Delta E/E = 6.6\%$. The instrument was mechanically scanned at a rate of 1° per second through an arc of 120° centred on a direction in the ecliptic plane 6° east of the spacecraft–Sun line. The field of view is fan shaped, ±13.5° in a plane containing the scan axis and ±3.5° in a plane perpendicular to the scan axis, which is maintained in the direction of Canopus by the attitude-control system of the spacecraft. The instrument obtains an electron spectrum every 6 s, from which the density, temperature and so on can be obtained[1].

Figure 1*a* shows an isometric view of the Mercury III trajectory and Fig. 1*b* a view from the Sun of the trajectories at both Mercury I and III, with the locations of observed plasma features marked. Entering and leaving the interaction region at each encounter, the plasma instrument detected the bow shock, the magnetospheric boundary and the intervening shocked solar-wind plasma (the magnetosheath). Within the magnetosphere, distinctive plasma electron populations were observed which exhibited large spatial and/or temporal variations. The magnetospheric populations observed at the two encounters differed significantly (Fig. 1*b*). Figure 2 shows electron fluxes in two energy channels for both encounters. Features labelled in Fig. 1 are identified here with vertical lines. The plasma signatures for the bow shock, magnetosheath and magnetospheric boundary seem to be similar in character at both encounters[1]. In the magnetosphere the Mercury I data show a transition between a cooler and a warmer electron population on the inbound and outbound trajectories. The Mercury III magnetospheric data show a sequence beginning with a cool plasma followed by a region of low fluxes in all energy channels and then returning to a cool electron population.

Spectra of the electrons from different plasma populations observed during Mercury III are shown in Fig. 3*a*, and a comparison with the "hot plasma sheet" spectra from Mercury I is made in Fig. 3*b*. The solar-wind spectrum exhibits the characteristic two-temperature profile. The expected increase in flux at all energies behind the bow shock is evident in the magnetosheath spectrum. The spectra of the "cool plasma sheet" populations measured at the two encounters are similar at energies above approximately 50 eV, but are quite different at lower energies; this difference is tentatively attributed to spacecraft charging. The plasma sheet is characterised by a flux above 100 eV which has a temperature even higher than that of the halo electrons in the solar wind, whereas the electrons in the low flux region have a temperature lower than those in the solar wind.

The magnetopause and bow shock were found in Mercury I to be geometrically similar to those of the Earth but reduced in size relative to the planet by a factor ~ 6. The present observations support this interpretation and provide further details of the plasma electron populations in Mercury's magnetosphere. Scaled up to the size of the Earth's magnetosphere, the Mercury I trajectory corresponds to a crossing of the Earth's magnetospheric tail from solar magnetospheric coordinates $X_{SM} \simeq -10R_e$ (Earth radii) and $Z_{SM} \simeq -3R_e$ on the dusk magnetopause to $X_{SM} \simeq -5R_e$ and $Z_{SM} \simeq 0R_e$ on the dawn magnetopause. The trajectory of Mercury III corresponds to a

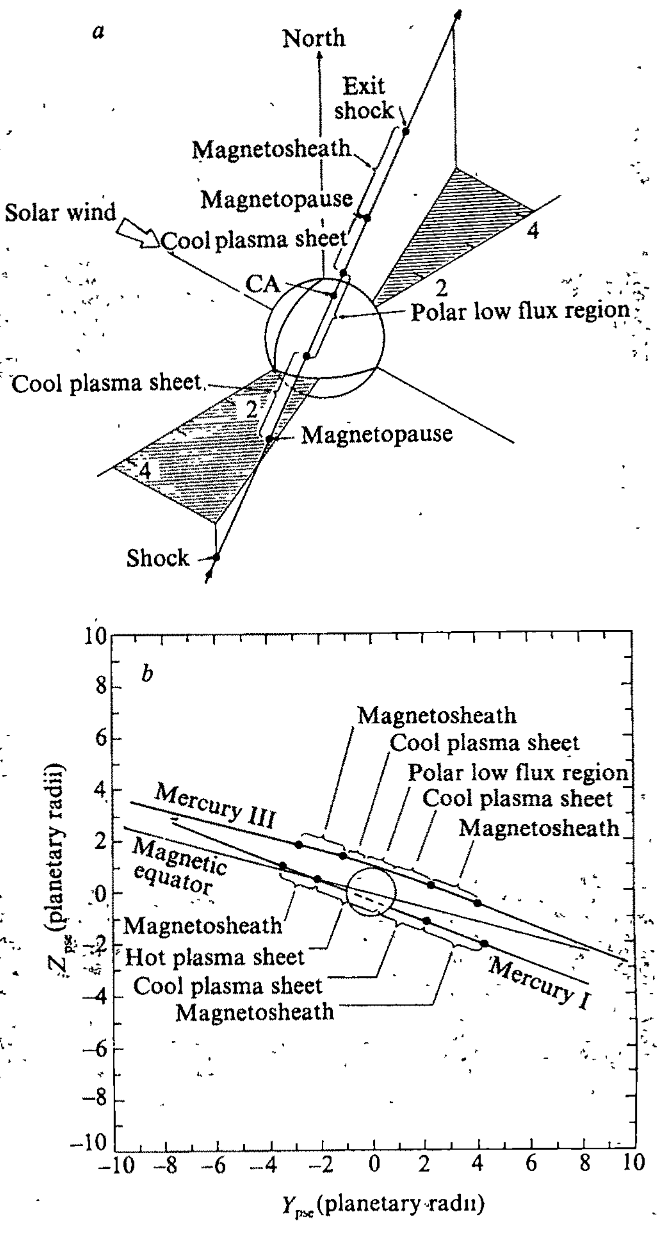

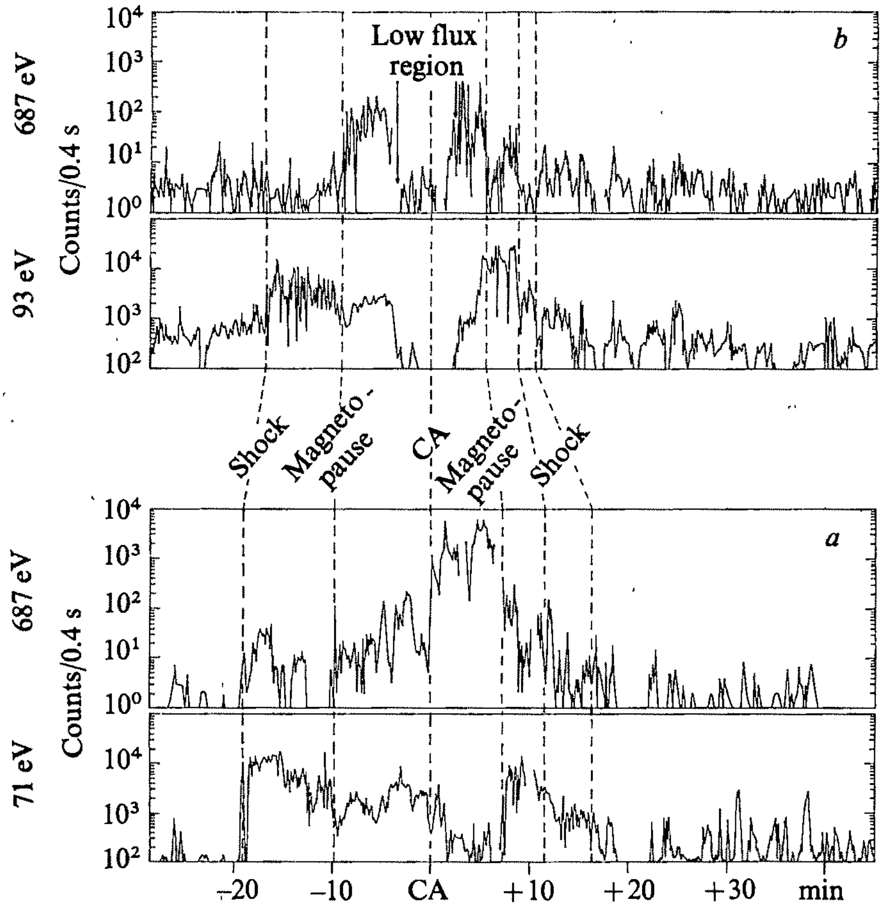

Fig. 2 Electron fluxes measured at 71 eV and 687 eV during Mercury I (*a*) and at 93 eV and 687 eV during Mercury III (*b*), with the bow shock, magnetopause and low flux region indicated by vertical lines. The curves have been aligned so that times of closest approach coincide.

similar crossing from $X_{SM} \simeq -6R_e$ and $Z_{SM} \simeq +4.5R_e$ to $X_{SM} \simeq 0R_e$ and $Z_{SM} \simeq +6R_e$. (The X_{SM} axis is the planet-Sun line. The Z_{SM} axis is positive northwards, defined such that the X_{SM}–Z_{SM} plane contains the dipole axis. These approximate solar magnetospheric coordinates are based on the Hermean magnetic dipole deduced from Mercury I magnetic field observations[2].) Both the present plasma observations and, in retrospect, those from Mercury I indicate large scale properties of the electron populations very similar to those which would be observed along scaled-up trajectories through the Earth's magnetosphere. The Earth's magnetospheric tail contains a plasma sheet centred about the solar magnetospheric (SM) equatorial plane and extending to a thickness of several R_e, characterised by a hot particle population (mean electron energy ≈ 1 keV) near the centre and a cool population (≈ 100–200 eV) near the edges; above and below the plasma sheet, on magnetic field lines connected to the polar caps, the particle intensities are very low. Figure 2 shows that all these regions have now been sampled at Mercury, at roughly the locations expected on the basis of scaling from Earth observations. The cool electron population observed at a relatively large distance from the SM equatorial plane by Mercury III is characteristic of the outer plasma sheet near the midnight meridian and at its largest distance from the SM equator, a region of low particle intensities which seems to be the analogue of the Earth's polar cap. At Mercury I, the spacecraft entered the magnetosphere at some distance from the SM equator and also observed a cool electron population, but on its outbound trajectory it was near the SM equator and observed a hot electron population similar to that in the central region of the Earth's plasma

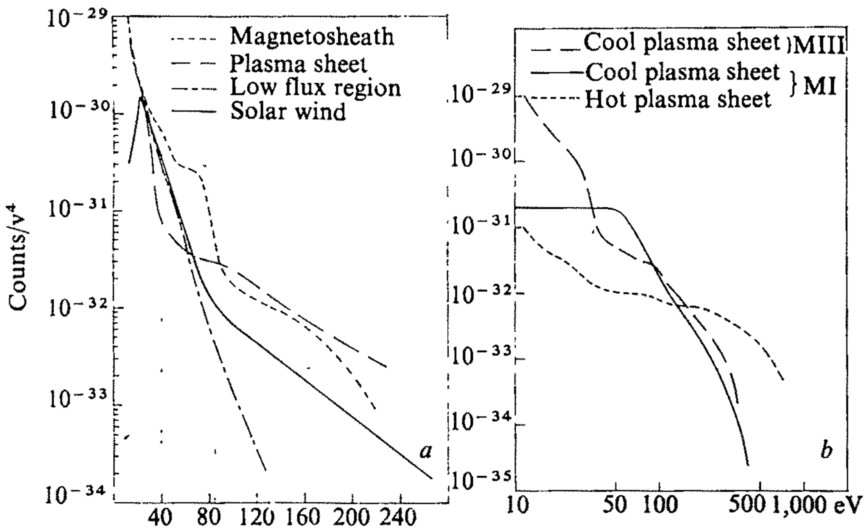

Fig. 3 *a*, Spectra of electrons observed at Mercury III. The vertical dotted line at 40 eV indicates distortion of the spectra below the energy as a result of spacecraft charging. The ordinate (counts/v^4) is proportional to the distribution function. *b*, Comparison between cool and hot plasma sheet spectra from the Mercury I observations with a cool plasma sheet spectrum from Mercury III.

sheet; as expected from its trajectory, it was never far enough from the SM equator to reach the low flux polar cap region.

The characteristic electron energy in the cool plasma sheet (Fig. 3*b*) observed in both Mercury I and III is $\sim$ 100–200 eV, whereas in the hot plasma sheet observed in Mercury I it is at least $\sim$ 1 keV; these energies are of the same order of magnitude as those observed in the corresponding regions of the Earth's plasma sheet. The fact that the plasma sheet energies in both magnetospheres are comparable implies that the plasma sheet energy does not scale with the electric potential difference across the magnetospheric tail, the value of which for Mercury should be about one-seventh of that for the Earth[3]; this has important implications for the still unsolved problem of the origin of the plasma sheet.

In summary, well defined bow shock and magnetospheric boundary crossings were observed on the inbound and outbound trajectories during Mercury I and III. The locations of the boundaries observed are mutually consistent with locations obtained from models which scale the Earth's magnetosphere to Mercury I data[1,4] and the other magnetospheric features are consistent with the magnetic field model[4]. Thus, the plasma results strongly support the idea that Mercury's magnetic field is intrinsic rather than induced, and show that the magnetosphere of Mercury is remarkably similar to that of the Earth.

Possible identification of Ariel 1118−61

THE transient X-ray source Ariel 1118−61 has been discovered by Ariel V (refs 1, 2) and the best estimate for the position is (1950.0) $\alpha = 11$ h 18 min 59s, $\delta = -61° 35.3'$. We point out here the presence in the error box of the long period Mira-type variable RS Cen (1950.0) $\alpha = 11$ h 18 min 16.5 s, $\delta = -61° 36.0'$. It has been suggested that in the Mira-type variables o Ceti (Mira) and SY For, the blue variable companion is a white dwarf illuminated by infalling material accreted from the strong wind of the M-type star[3–5]. The similarity between these systems and the (recurrent) nova T CrB has also been stressed[6]. We propose that some transient X-ray sources are binary systems consisting of a compact object in orbit around a long period variable. The accretion rate of material on to the compact object in such a system[4] is $\lesssim 10^{-8}\ M_{\odot}\mathrm{yr}^{-1}$ which is just the rate required to produce X rays from a compact object. We note, too, the proposed identification[6] of another transient X-ray source (2U1543−47) with a variable late-type giant.

The large variability of radius and luminosity of a Mira-type star is likely to produce strong modulation of the stellar wind and a similar modulation of the accretion rate on to and thus luminosity of the compact object. A similar correlation between stellar wind strength and luminosity of the X-ray object has been proposed for Cen X-3 (refs 7, 8). We expect the modulation to be much stronger for Mira-type stars.

The transient source A1118−61 was observed to peak in mid-December 1974. The period of RS Cen is[9] 164.51 d and the X-ray source appeared at phase $\sim$ 0.4 (optical maxima occur at phase 0.0 and minima at 0.54) of the cycle when the radius of RS Cen is expected to reach a maximum. We intuitively expect mass outflow to be greatest near light minimum, when absorption bands are strongest in the stellar atmosphere. If the proposed identification is correct we expect the transient X-ray source to appear 'regularly' with a period of 164 d. Eclipses of the compact object by the red variable may complicate this prediction: the orbital period for such a system is $\gtrsim$ 2 yr. We would associate the 6.75 min periodicity of the X-ray object with the rotation (or possibly precession) period of the compact object[10].

The identification of A1118−61 with RS Cen would establish the identity of a new class of X-ray binaries. Such systems would offer a unique opportunity to study the structure and dynamics of the atmospheres and winds of Mira-type variables.

Observations of low energy gamma-ray bursts with SAS-2

Low energy celestial gamma ray bursts were discovered[1] in 1973 and the detection later confirmed by several groups. In this paper we report the low energy gamma-ray bursts observed by the plastic scintillator anticoincidence dome of the Small Astronomy Satellite-2 (SAS-2) gamma-ray telescope. Although the high energy gamma-ray telescope of SAS-2 has a threshold of about 20 MeV, the large SAS-2 anticoincidence dome (A-dome), which is the outermost element of the instrument, provides a very large detector for the high energy portion ($\geqslant$0.3 MeV) of these burst events.

Details of the instrument are given by Derdeyn *et al.*[2]. The A-dome, constructed out of 1.5 cm thick scintillator has an average collection area of about 2.5×10^3 cm^2 and is an almost omnidirectional detector, only being insensitive to directions within a small cone ($\sim$30° half angle) centred around the direction that it is attached to the spacecraft. The average effective threshold for detection over the dome is about 0.15 MeV, the average efficiency rising to about 20% at 0.6 MeV. The counting rate of the A-dome is accumulated and read out every 768 ms. When there is no increase resulting from the trapped radiation in the Atlantic anomaly, the observed rate is about 4.2×10^3 counts s^{-1} and it remains quite steady. (The Earth's trapped radiation extends downward to unusually low altitudes in the central

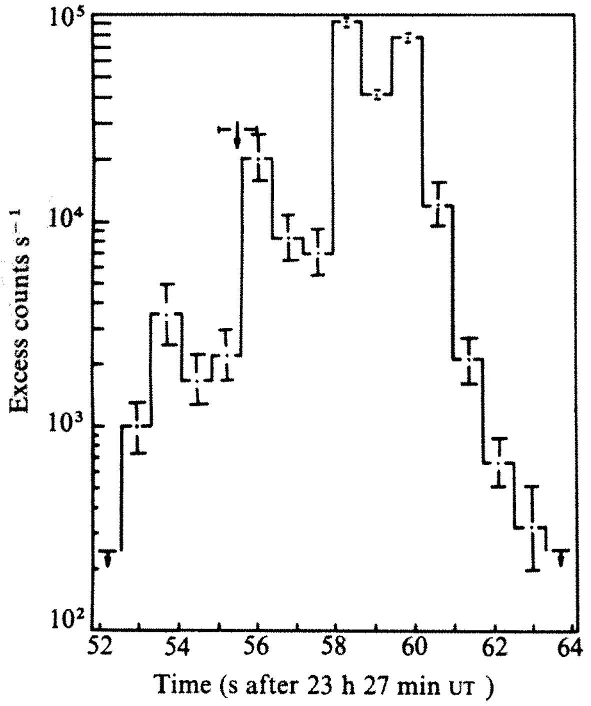

Fig. 1 Time history of the low energy gamma-ray burst observed in the SAS-2 A-dome on March 2, 1973. The arrow shows the event time observed by the Vela satellites. The counting rates shown are the excess counts above the steady SAS-2 background of 4.2×10^3 counts s^{-1}.

and south Atlantic. These low energy electrons and protons cause an increase in the count rate of the A-dome.)

SAS-2 was launched on November 15, 1972 into an equatorial orbit with a 440-km perigee and 610-km apogee. During the period of experimental operation (November 20, 1972–June 8, 1973, the counting rate from the A-dome provided a continuous monitor for fluctuations in the low energy gamma-ray fluxes from the unocculted sky. Using these data a search has been made for sudden rate increases where there is an excess of 600 counts or more over the background in at least three successive 0.768 s readouts. Although this criterion would not pick up events with time scales shorter than 2 s, the occasional noise spikes in single readouts made its adoption necessary. The selection criterion is further biased against events which last longer than 30 s because of background comparisons which were made on this time scale.

This procedure resulted in the detection of two events observed by other satellites and the discovery of one, which has now been confirmed by other satellite observations. In addition, two events on the list of those detected by the Vela satellite series[3] were not seen by SAS-2. In view of the high sensitivity of SAS-2, these negative results suggest that the Earth occulted the source, as it will, on average, 40% of the time. Table 1 lists the five events that have been confirmed as multisatellite observations. There was no reported solar activity during any of these events.

Considering the two events not seen by SAS-2, if it is assumed that the absence of a detectable signal in the SAS-2 A-dome is an Earth occulation effect rather than a large variation in the expected energy distribution, then the regions of the sky in which the events occurred may be restricted regions. These are a 70° cone about $\alpha=36.6°$, $\delta=1.0°$ in the case of the December 18, 1972, event and a similar cone about $\alpha=27.4°$, $\delta=1.6°$ in the case of the May 7, 1973, event. For the December 18, 1972, event this cone is consistent with the location of the source lying in the region $70°<\alpha<120°$, $0°<\delta<20°$ as determined by Imhof *et al.*[4] except that it excludes the highest part of the α range. The time history of the March 2, 1973, event as measured by SAS-2 is shown in Fig. 1. Notice that the time given by the Vela satellites for the first detection of an increase is well into the event. These data support the point of view that the gamma-ray bursts observed have a complex time structure and may have durations in excess of those measured by Vela type detectors that trigger on sudden increases[4].

Even with the SAS-2 time resolution, four distinct peaks appear indicating a significant temporal structure (Fig. 1). The event reaches a peak intensity of 9.4×10^4 counts s^{-1}, more than two orders of magnitude greater than the threshold of 7×10^2 counts s^{-1} which the event must surpass in the 0.768 s readout interval in order to be selected in the computer scan of the SAS-2 data. Considering the occultation of SAS-2 by the Earth, the event must have occurred in a region of the sky within a cone of 110° around $\alpha=49.4°$, $\delta=0.1$. The Vela data (R. W. Klebesadel, R. A. Olsen and I. B. Strong, private communication) indicate the source was in a circular band of radius $82.5\pm4°$ centred at $\alpha=193.9°$, $\delta=25.7°$.

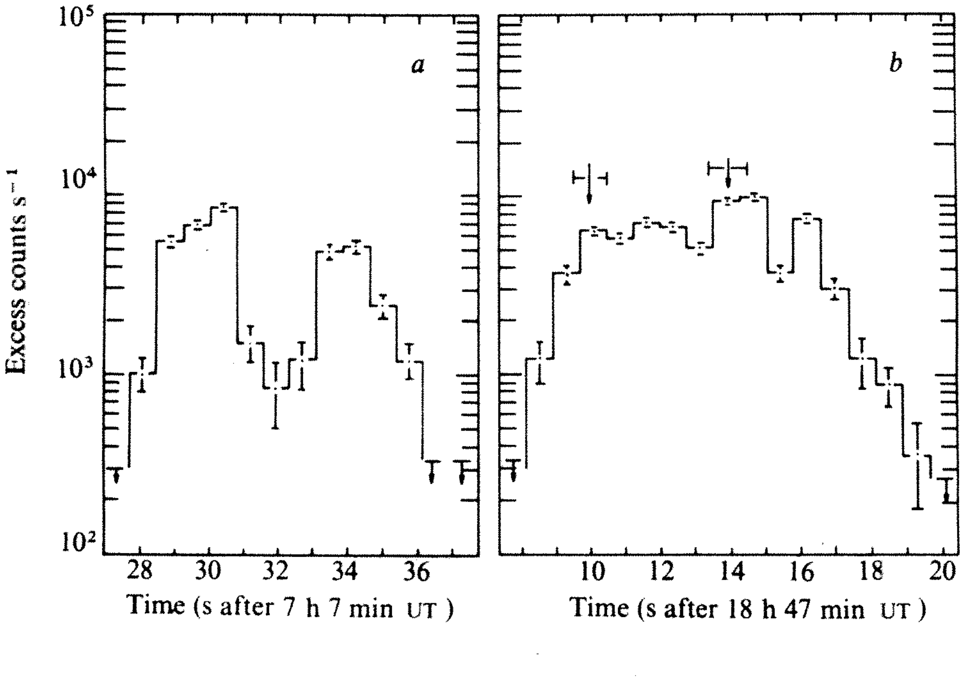

Fig. 2 Time histories of two gamma-ray burst events seen by the SAS-2 A-dome on June 6, 1973. The arrows show the event times observed by the Vela satellites. *a*, Vela 5A; *b*, Vela 6A. The counting rates shown are the excess counts above the steady SAS-2 background of 4.2×10^3 counts s^{-1}.

Post Graduate Library
SCIENCE COLLEGE
92 Upper Circular Road
CALCUTTA

Two events seen by SAS-2 occurred on the same day, June 6, 1974, which is surprising considering the average event rate. The time profiles of these two events are shown in Fig. 2. There were only 12 detected cases in the approximately 6.5 months that the A-dome rate exceeded the threshold level and remained above background (by $>6\times10^2$ counts s^{-1}) for more than three readout intervals (approximately 2.3 s) except when the satellite passed through the Atlantic trapped radiation anomaly. The second June 6 event was subsequently confirmed by the IMP-7 satellite[5] and the Vela system (Table 1). Notice that again for the June 6 event which did trigger the Vela system the Vela time for first detection occurs after the event has started and reached a level almost an order of magnitude above the SAS-2 threshold. Considering the occultation of SAS-2 by the Earth for the two June 6, 1973, events, the first must have occurred within 110° of $\alpha=184.1°$, $\delta=1.2°$ and the second within 110° of $\alpha=317.7°$, $\delta=-1.9°$. The other events observed by SAS-2, but not confirmed by other satellites, seem to be genuine events although the estimated fluxes are in the range of 3×10^{-8} to 10^{-5} erg cm^{-2} which may reduce the probability of detection by the other satellites involved.

Table 1 Confirmed multisatellite observations (November 20, 1972–June 8, 1973)

Date	Time h min s	Satellite and reference
December 18, 1972	20 27 39	2 Velas*; IMP-7[5]; 1972-076B[4]
March 2, 1973	23 27 53	2 Velas*; IMP-7[5]; SAS-2
May 7, 1973	08 04 32	3 Velas[2]
June 6, 1973	07 07 28	IMP-7[5]; SAS-2
June 6, 1973	18 47 08	SAS-2; IMP-7[5]; 2 Velas*

The satellite listed first is the one from which data first led to recognition of the event.

*Unpublished results from R. W. Klebesadel *et al.*

In view of the significant sensitivity of SAS-2 as suggested by these comparisons and direction calculations, it may seem surprising that no other events with timescales betwen 2 and 30 s were observed; however, it is difficult to draw quantitative conclusions from this result because of the difficulty of comparing results from detectors with vastly different characteristics.

In none of the events was there any significant excess of high energy gamma rays in the spark chamber. This is not surprising since with the 0.25 sr solid angle of the high energy telescope, there is less than a 5% chance that an event will fall within the telescope acceptance angle even if there is a detectable flux of gamma rays with energies above 25 MeV.

We thank Drs Klebesadel, Strong and Olsen for providing unpublished Vela data and Drs Cline and Desai for reviewing the IMP-7 data to determine the existence of events at the times suggested by the SAS-2 data. H. Ö. is an NRC Senior Postdoctoral Associate.

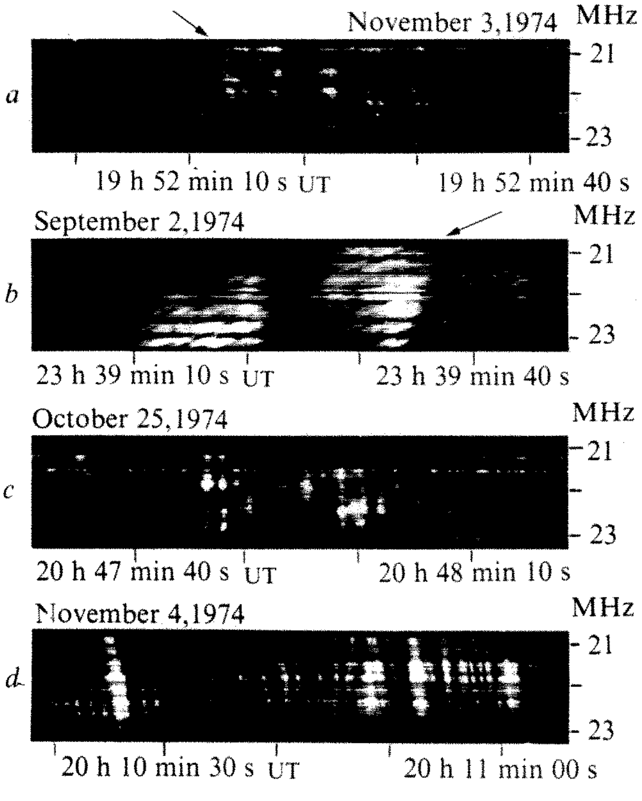
Polarisation structure of Jupiter's decametre radio bursts

THE high-resolution dynamic spectra of Jupiter's decameter radio emission exhibit structures consisting of repeated, tilted ridges[1]. The frequency–time slope of these 'diagonal patterns', also referred to as modulation lanes, varies from 50 to 300 kHz s^{-1}. The slope is a function of the System III central meridian longitude of Jupiter, and it may be either positive or negative[2,3]. Recent observations of modulation lanes are described by Ellis[4,5] and Lecacheux[6]. Here I report a study of polarisation diversity in the spectra of modulation lanes.

The frequency range 21–23 MHz is close to the region above which the Jovian bursts are predominantly elliptically polarised in the right hand (RH) sense, but below which the proportion of bursts polarised in the left hand (LH) sense increases. Since most of the spectra of the lanes have been recorded in RH circular or linear polarisation, no conclusive information on the relationship of the modulation lanes to polarisation is available[7].

Rapid reversals of the sense of polarisation have previously been observed in spectral records of groups of S bursts[8]. The phenomenon occurred as a function of time and frequency, and was referred to as 'polarisation diversity'. This polarisation diversity has been observed[9-12] in fixed frequency records of L-bursts. The reversals of polarisation sense were often cyclic with time. To study the function of diversity in modulation lanes, the spectra of the RH and LH circular components must be recorded separately, as in the experiment reported here.

Fig. 1 Samples of high-resolution spectra of Jupiter's decametre radio bursts. Modulation lanes are shown in *a* (positive drift) and *b* (negative drift) indicated by arrows. The durations of the envelopes are long in *b* but short in *c*. The envelopes seem to be tilted in *d*. The wide, parallel horizontal lanes are residual Faraday fringes. In *b* the antenna polarisation was linear and the Faraday fringes seem to be very strong.



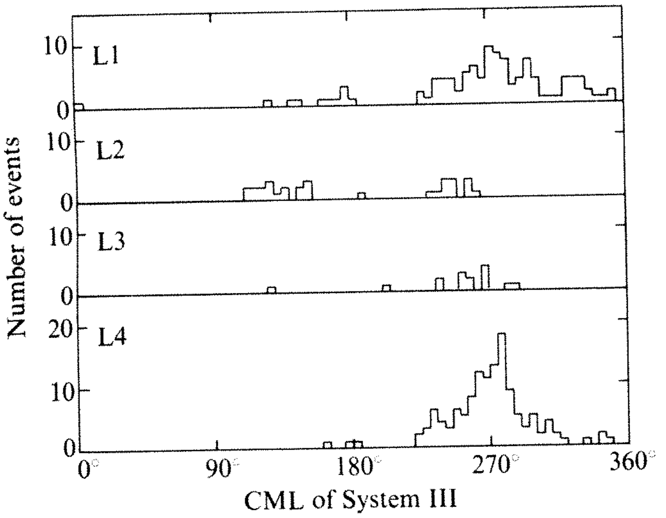


Fig. 2 Number of events of types L1 to L4 as a function of System III (1957.0) central meridian longitude (CML).

A new instrument was built for this purpose, the antenna of which is a steerable system of two cross log-periodic units in parallel. The circular components are obtainable with broadband quadrature hybrid circuits. The main equipment is a 48-channel receiver for the range 20.85–23.10 MHz. The channels are separated by intervals of 50 kHz and have 3 dB bandwidths of 15 kHz, with a signal integration time constant of 20 ms. The display unit consists of a two-colour (red and green) array of 96 light-emitting diodes, switched at a rate of 1 kHz in synchrony with the radio frequency switch at the output ports of the hybrid circuits.

The sense of polarisation is indicated by the colour of the spectrum, since colour is the only extra dimension available in an intensity-modulated frequency–time representation. The recording is made on a 16 mm colour reversal film. If the emission is highly elliptical, the amplitudes of the RH and LH components are almost equal, and the resultant colour is yellow. For highly circular emissions in the RH or LH sense, the spectrum appears green or red, respectively. Slight variations in colour can be detected faster and with greater confidence than small density differences in two parallel black-and-white records.

The observations were carried out from August 1 to November 17, 1974, for 2 h each night at Kiiminki, 30 km east of Oulu. Other spectrographs of the sweep-frequency type were operated simultaneously. Only the multichannel observations are described here. Some interference was caused by residual Faraday fringes. Because of the relatively low altitude of Jupiter (15–18°), the effect of ground reflection could not be avoided. Thus the Faraday rotation modulated the axial ratio of the polarisation ellipse and the relative amplitudes of the circular components.

Sample records reproduced in black-and-white are shown in Fig. 1. Prominent features in the spectra are the radiation areas (envelopes). The modulation lanes traverse them diagonally in a continuous manner. According to the classification given previously[2], *a* and *b* represent bursts of types L2 and L4, respectively. In the same notation L1 indicates a burst with no detectable lane structure, and L3 a burst in which the positive and negative lanes are superposed.

The durations of the envelopes are related to the elongation of the planet; towards opposition the durations tend to increase[3]. Accordingly, the duration of envelopes in Fig. 1*b* are longer than those in Fig. 1*c*. 'Fast-drift lanes' are observed occasionally, with frequency–time slopes an order of magnitude greater than those of the modulation lanes (Fig. 1*d*). Similar events have been recorded by Ellis[5,13].

An occurrence histogram of bursts of types L1 to L4 is presented in Fig. 2. This is constructed in the same way as that for the 1966–69 observations[3]. Again, type L4 bursts are associated chiefly with regions A and C, and type L2 bursts with region B. But the number of L1 bursts relative to bursts of other types is greater than before, the number of L2 and L3 bursts is less, and bursts of type L3 occur chiefly at region A rather than at region B. The region designation is that of Carr, *et al.*[14].

The result of a careful search for polarisation diversity effects indicates that diversity does not occur as a rule in the spectra of modulation lanes. Most lanes are simple variations in intensity of emission, and thus are similar in appearance in both circular modes. The polarisation is elliptical in the RH sense and the amplitude of the RH component is the larger of the two.

There are a few cases in which diversity does appear. The sense of polarisation is then LH, and may be recognised easily from the colour. Polarisation diversity seems to occur in areas where the amplitude pattern of the spectrum is more complex than just a simple set of lanes. In two such spectra obtained it seems that the LH component may belong to one of the two sets of lanes of the L3 burst. Not all of the L3 bursts, however, display polarisation diversity.

Wear of synthetic diamond when grinding ferrous metals

It is well established that diamond is an inefficient abrasive for grinding ferrous materials, especially the low carbon variety. The widely held view is that as ordinary carbon has a strong affinity for iron, forming iron carbide (Fe_3C), this should also be the case with diamond (cubic carbon) when grinding steel. The high rate at which diamond grinding wheels wear down when grinding low carbon steel is said to be a consequence of this action. We suggest here another mechanism, evidence of which is provided by scanning electron micrographic (SEM) data.

To simulate grinding and at the same time eliminate the influence of the bonding material, cutting tests have been performed using a single diamond particle mounted on the periphery of a 20 cm (8 inch) diameter aluminium disk. A groove was cut in a soft, low carbon, steel plate (AISI 1018 steel) by moving the flat plate into the rotating diamond particle at a speed v. This method of simulating the action of an abrasive particle in the surface of a grinding wheel is termed overcut fly milling[1,2]. The machine settings—table speed, v: 30 cms^{-1} (12 inches min^{-1}); downfeed (depth of groove), d: 25 μm (0.001 inch); and disk speed, V: 20.3 ms^{-1} (4,000 feet min^{-1})—were chosen to give a chip size comparable to that used in fine surface grinding using a diamond grinding wheel (resulting in an undeformed chip thickness of a few microns). A well developed, single crystal, synthetic (cubo-octahedral) diamond was chosen for study. This type of diamond was

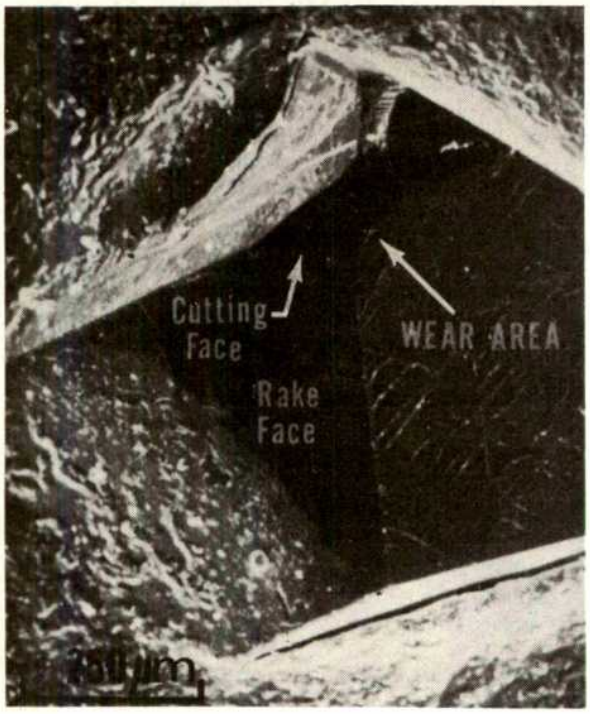

Fig. 1 Micrograph of the wear area of a diamond grit.

selected in preference to a polycrystalline specimen because it is considerably stronger and less inclined to chip by intercrystalline fracture. This combination of tool and method precluded diamond wear by chipping.

Several thousand cuts were made on the work material with each diamond particle tested. After a test, the worn diamond surface was coated with a thin layer of gold–palladium (to overcome the charging problems otherwise experienced in the scanning electron microscope) and the wear areas were examined.

Figure 1 is a micrograph of the worn area of a diamond grit examined in the secondary electron mode. Figure 2 is a micrograph of the worn area obtained by tilting the sample favourably and examining it in the back scatter mode. The worn area is not plane but has a concave shape in a direction transverse to the direction of cut. Figure 3 shows the groove-like markings evident in Fig. 2 at higher magnification. These markings result from a transverse saw tooth pattern (Fig. 4). No wear was evident on the rake face of the diamond across which the chip flows under high pressure.

All of the results described here are consistent with a mechanism of wear in which diamond is converted to graphite before its removal from the worn surface.

Diamond at room temperature is in a metastable state and will transform to graphite in the proper circumstances. An increase of temperature without a suitable increase in pressure will carry the diamond further from equilibrium and the presence of a properly directed shear stress will promote further the transformation to graphite. The presence of a material that rapidly removes graphite from the surface of the diamond should promote this transformation even more. Hot, low carbon steel is such a material. This latter situation does not arise when grinding aluminium or copper alloys with diamond and, consequently, the rate of wear is negligible in those circumstances.

All of these conditions (high temperature, relatively low pressure, high shear stress and hot iron) are present on the worn area on the clearance face of a diamond abrasive particle that is cutting soft, low carbon steel.

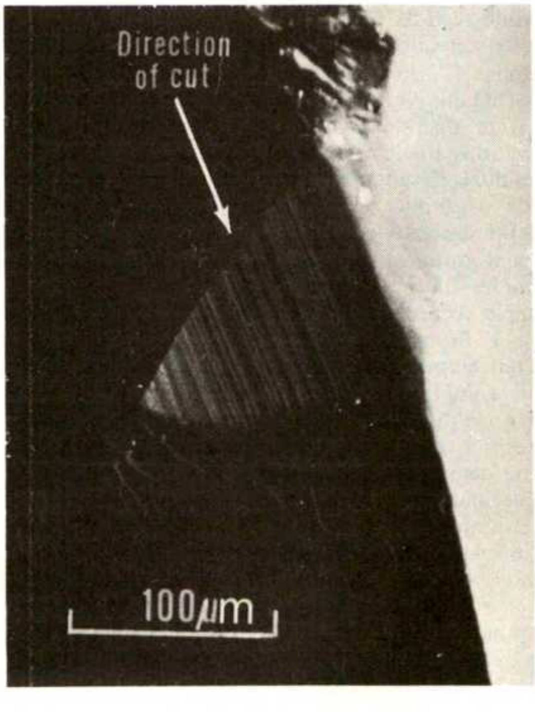
The fact that diamond (unlike graphite) is relatively insoluble even in molten iron (a key point in the synthesis of diamond[3]) rules out the possibility that diamond reacts directly with iron.

Once diamond graphitises, however, the graphite so formed can rapidly diffuse into iron because of the intimate contact under pressure, the high affinity of graphite for iron and the high interfacial temperatures. Also, the fact that diamond is worn more rapidly by a soft, low carbon steel than it is by a strong, highly alloyed steel, tends to rule out oxidation as the major cause of diamond wear since the alloy steel would give rise to a higher grinding temperature.

The grooves evident in Figs. 2 and 3 could not have been produced by direct abrasive action of any constituent in the soft steel being ground. Instead, those grooves must result from a preferential transformation on 110 planes, as shown in Fig. 4. Prins *et al.*[4] have reported similar markings on diamonds used to grind hardened tool steel (AISI M42) but were unable to explain their presence. Experiments conducted by Seal[5] has shown that the 001 faces of diamond were the most resistant to high temperature thermal graphitisation whereas the 110 planes were the least resistant. Bovenkerk *et al.*[6] have reported that diamonds grow with cubic habit when the conditions of temperature and pressure are almost minimal for a particular catalytic-solvent material, but that they grow with octahedral habit when the temperature and pressure are very much higher. As Seal[5] has pointed out, the directions of fastest graphitisation are the same as those of the fastest growth, and the directions of slowest graphitisation coincide with those of slowest growth in the lower pressure part of the region of diamond synthesis. These striking similarities suggest strongly that the catalytic-solvent effect of iron, and the concomitant conditions of high temperature and lower contact pressures (relative to the stable region of the diamond) when grinding low carbon steel with diamond, play a very significant role by causing rapid, preferential graphitisation of diamond, leading to poor grinding performance.

The sharp lines evident in Figs 2 and 3 on the worn areas are approximately parallel but do change direction and intersect occasionally. These lines are thought to be the ends of what Tolansky[7] refers to as slip planes (found in man made diamonds) which are akin to the foliation markings in natural stone that has been subjected to plastic flow under enormous pressure. It is of interest to note that the spacing of these slip

Fig. 2 Micrograph of the same wear area obtained by tilting the sample and examining in the back-scatter mode.



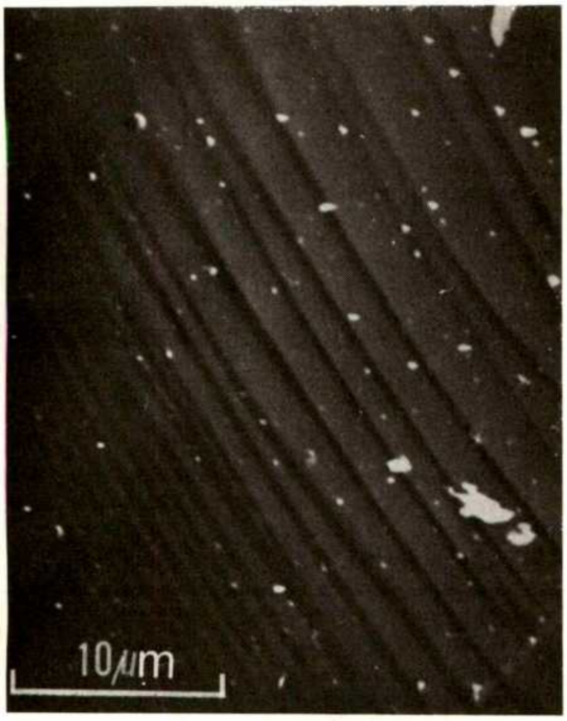


Fig. 3 Groove-like markings in the wear area of diamond grit.

planes is from 1 to 3 µm in the samples of diamond used in this investigation.

The concave shape of the general wear surface is also consistent with the graphitisation theory of wear presented here. The temperature in the central region of the cut will be higher than at the edges and this should give rise to a higher rate of graphitisation in the former region.

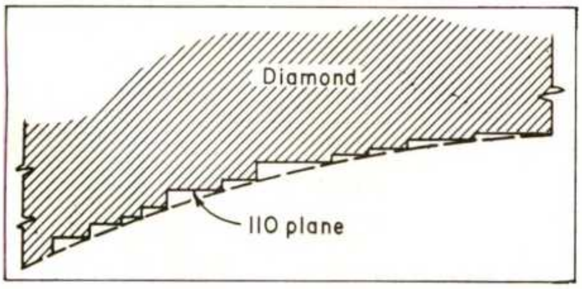

Fig. 4 Graphical representation of saw-tooth markings shown in Fig. 3.

Chemistry and structure of high pressure phase of garnets rich in almandite

I HAVE previously reported[1,2] high pressure phase transformations for garnets of the almandite–pyrope ($Fe_3Al_2Si_3O_{12}$–$Mg_3Al_2Si_3O_{12}$). Here, the chemical formula and the crystal structure for the high pressure phase of almandite-rich garnets quenched from a loading pressure of approximately 120×10^5 kPa and temperatures of about 1,400–1,800 °C are given.

Details of the samples and experimental procedures have been described elsewhere[3,4]. Fine polycrystalline powder samples of synthetic almandite and natural almandite-rich garnets were compressed in a diamond anvil press fitted with a lever and spring assembly and were irradiated by a continuous wave YAG laser. The loading pressures of the sample at the central portion of the anvil were estimated from the length of the spring which was calibrated according to the room temperature NaCl pressure scale. The real pressure to which the sample was subjected is probably $\sim 40 \times 10^5$ kPa greater than the loading because of a transient increase of pressure during heating. The temperatures of the samples could be estimated using an optical pyrometer but the uncertainties would be rather large.

The quenched samples have been X rayed with CoKα radiation in a modified 57.3-mm Debye–Scherrer camera. The resultant diffraction data have been listed in Tables 1 and 2 for the synthetic almandite–garnet and the natural almandite-rich garnet. With the exception of the reflection at $d = 2.95$ Å, nearly 40 observed d-spacings for the high pressure product from synthetic almandite can be indexed on the basis of a structure isotypic with the hydrogarnet, griphite[5,6]. Many reflections such as 2.866, 2.559, 2.444 Å . . . , which seemed initially to be those of the starting material, almandite, can equally well be derived from the new high pressure phase. This is evident from comparison of the observed d-spacings with those calculated for almandite and for the griphite isotype. The calculated lattice parameter for the high pressure phase with the griphite structure is $a_0 = 11.470 \pm 0.025$ Å. The space group may be $P2_1/a\bar{3}$ (ref. 6). The reflection of 2.95 Å may correspond to the most intense reflection (110) of stishovite. Thus, almandite seems to disproportionate into a mixture of stishovite plus a phase with the griphite structure at approximately 120×10^5 kPa loading pressure and 1,400–1,800 °C. With the exception of a very weak unidentified line, 2.071 Å, the high pressure phases for the natural almandite-rich garnet (Table 2) are almost identical to those of the synthetic almandite with the lattice parameter for the griphite structure $a_0 = 11.465 \pm 0.030$ Å.

Griphite is a hydrophosphate garnetoid. Its chemical formula represents a complex example of a general form of $X_3Y_2(ZO_4)_{3-m}(OH)_{4m}$ with $m = 0.5$ (ref. 5). Because no water was involved in this study of phase transformations of garnet[2], one would expect the general formula for hydrogarnets to be modified to suit the possible chemical formula of the high pressure phase of almandites. Removing water completely, $2m(H_2O)$, from the general form of hydrogarnet yields another general formula of $X_3Y_2(ZO_4)_{3-m}(O)_{2m}$. If the high pressure phase with griphite structure has this formula, then the high pressure disproportionation of almandite can be represented as

$$\underset{\text{garnet}}{Fe_3Al_2(SiO_4)_3} > \underset{\text{griphite}}{Fe_3Al_2(SiO_4)_{3-m}(O)_{2m}} + \underset{\text{stishovite}}{mSiO_2}$$

Stishovite is indicated by the diffraction patterns (Tables 1 and 2), confirming the proposed reaction. The precise value for

Table 1 Room temperature and 1 bar pressure X-ray diffraction data of synthetic almandite quenched from a loading pressure of approximately 120×10^5 kPa and 1,400–1,800 °C (CoKα).

*Estimated visually. The question mark denotes extremely weak lines.

†Observed in a standard Debye–Scherrer film with the exception of the last three reflections. *d*-spacings were calculated on the basis of $a_0 = 11.532$ Å reported by Takahashi and Liu[3].

‡Calculated from $a_0 = 11.470$ Å (see text).

§From Chao *et al.*[7].

m is not known at present, but the maximum value can be calculated since

$$\underset{(115.45\ \mathrm{cm^3\,mol^{-1}})}{V^0\text{almandite}} \geqslant \underset{(113.60\ \mathrm{cm^3\,mol^{-1}})}{V^0\text{griphite}} + m \underset{(14.03\ \mathrm{cm^3\,mol^{-1}})}{V^0\text{stishovite}}$$

where V^0 is the standard molar volume. So $m \leqslant 0.13$. The observed relative intensities for griphite and stishovite in Tables 1 and 2 support this estimate. If $m = 0.10$, the volume change associated with the disproportionation of almandite is -0.4%.

The quantity of stishovite in the products is expected to be very small, the evidence of its presence is rather weak since only one reflection line has been found to correspond to the most intense line of stishovite. An alternative explanation would be that this weak line (2.95 Å) may be derived from one of the intermediate phases between the griphite and the perovskite structures[1,2]. The observed griphite form may, therefore, be a stoichiometric $X_3Y_2(ZO_4)_3$ compound with the associated volume change for the polymorphic phase transition being -1.6%.

The high pressure phase of griphite structure found in this study is probably formed within a pressure range of 100–150×10^5 kPa. This pressure can be created naturally by meteorite impact, which seems to be the origin of mineral stishovite. Rocks containing a high proportion of almandite, such as mica and other schists, that have been subjected to

Benthic nutrient regeneration and its coupling to primary productivity in coastal waters

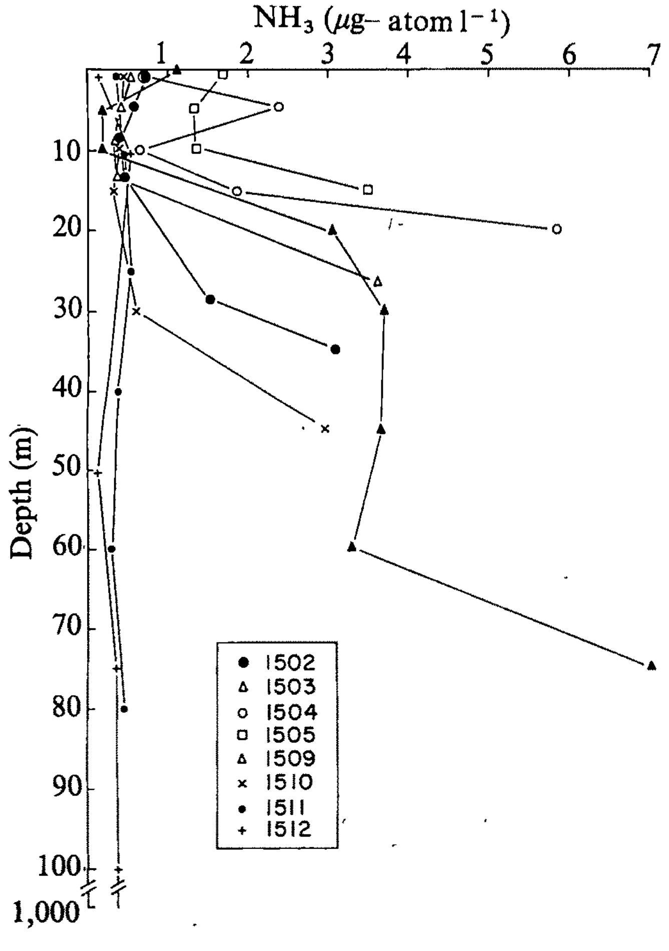
SHALLOW, near-shore ocean waters support high primary production because of the availability of inorganic nutrients. The availability is usually attributed to the proximity of freshwater runoff or to coastal upwelling and deep water advection[1,2].

The effects of nutrient regeneration from the ocean bottom have not, however, been estimated. We report here the first successful attempts to measure directly the nutrient flux from nearshore sediments. We contend that the continental shelf itself is a tightly coupled component of most near-shore ecosystems and that the function of the shallow sea floor in nutrient regeneration has been underestimated in previous investigations.

Nitrogen is considered to be the element limiting photosynthesis in coastal waters[3]. Although it has been presumed that the bottom is an important site of nitrogen remineralisation[4], attempts to estimate benthic regeneration have been confined to lakes[5,6], indirect inferences from concentrations[7,8] of pore water, or laboratory incubations which indicate that the bottom is only a minor source of nutrients[9] or even a nitrogen sink in anoxic areas[10].

It is necessary to know the rate at which ammonia and nitrate diffuse into the water column from the sediment to determine the degree of coupling between the bottom and primary production in the water. An indirect method which we have used is the assumption that the breakdown of organic matter in sediment is proportional to the amount of oxygen required by the sediment[11,12] although that probably, to some degree, underestimates total catabolism[13]. For each millilitre of oxygen consumed, we assumed that 0.412 mg organic carbon was oxidised to CO_2. The organic carbon–nitrogen ratio in sediments is about 10:1, or greater, and therefore we assumed that 0.041 mg organic nitrogen would be remineralised to ammonia for each millilitre of O_2 consumed. Numerous measurements of the amount of oxygen required by the sediment have been made and it is, therefore, relatively easy to estimate the degree of ammonia production of the bottom in many regions. The oxygen demand of the sediment in the sublittoral zone ranges from about 1 to over 100 ml $m^{-2} h^{-1}$ (ref. 12) and, therefore, 0.041–4.1 mg NH_4 $m^{-2} h^{-1}$ (2.0–292 μg-atom NH_4) should be produced by excretion.

Fig. 1 Concentrations of ammonia in the water column at selected locations on the continental shelf off New York, September, 1970 (ref. 3 and N. Corwin, unpublished). Stations 1504 and 1505 are the New York City sewage sludge dump site and the Army Corps of Engineers dredge spoils dump site, respectively. The terminal datum point on each profile is from the bottle, several metres above the bottom.



We presumed that if the predicted regeneration occurred it would diffuse out of the bottom. We therefore carried out *in situ* experiments to test this. An opaque, 7.5-l bell jar, with a stirring motor and an O_2 electrode[14], was used to incubate a 730 cm^2 area of the bottom for various lengths of time. (The stirrer circulates the water at a velocity somewhat less than natural tidal currents—up to 15 cm s^{-1}—and it maintains exchange over the electrode.) Periodically, we withdrew water samples from the jar and measured the concentrations of ammonia, nitrate, nitrite and phosphate accumulating within the enclosure[15].

The amount of ammonia evolved was quite large (Table 1). Both the oxygen demand of the sediment and ammonia production were highly dependent on temperature. The November experiment came closest to a yearly average temperature and to what we would expect is an average oxygen demand (22.08 ml $m^{-2} h^{-1}$), corresponding to a production of 0.91 mg N (64.6 μg-atom $m^{-2} h^{-1}$), which was close to that actually measured (69 μg-atom $m^{-2} h^{-1}$) evolving into the bell jar. Most of the nitrogen at warmer temperatures was in the form of ammonia. At lower temperatures, some had been oxidised to nitrite and nitrate, suggesting there may have been loss of nitrogen from the system by denitrification to N_2 (ref. 10). On average, 81% of the nitrogen predicted to return to the water did so. Possible sources of error were nutrient uptake by plants in the bell jar, lower-than-normal diffusion out of the mud, or ammonia binding by cation exchange to clay particles[16].

Because nutrients from freshwater could not account for the high near-shore productivity, Riley[1] proposed a model which moved deep nutrients onshore by horizontal advection and tidal mixing. This mechanism is not needed to account for the productivity gradient if benthic feedback (recycling) is included in the system. Bottom respiration on the continental shelf should be near 10–20 ml $m^{-2} h^{-1}$ (refs 11, 12, 14 and 17). This means that 4.12 mg organic carbon and 0.412 mg organic nitrogen (29.4 μg-atom N) would be oxidised to CO_2 or deaminated to NH_4^+, respectively. If about 80% of the NH_4^+ were released from the sediment, the average feedback for the continental shelf would be about 23.5 μg-atom N $m^{-2} h^{-1}$.

We cannot yet confirm this by *in situ* measurements on offshore, continental shelf sediments, though there is strong evidence that our indirect estimates are close to reality (ref. 3, and N. Corwin, unpublished). Ammonia concentrations at continental shelf locations in late summer 1969, south of Long Island (Fig. 1) increased by about 2.5 μg-atom l^{-1} in the bottom 10–15 m of the water column. This gradient was probably maintained by photosynthesis below the thermocline and by vertical eddy diffusion. The flux along the gradient can be represented by a finite difference equation:

$$\text{flux of ammonia} = K\,(\text{change in concentration/change in depth})$$

where K is a 'mixing constant' with values ranging from <1 to >100 (cm^2 s^{-1})[18]. Over a typical sand bottom (Stations 1502, 1503, 1510, Fig. 2) the average near-bottom gradient was about 0.2 μg-atom NH_4^+ l^{-1} m^{-1}. Using 2 cm^2 s^{-1} for K (see ref. 18) we estimate that 144 μg-atom NH_4^+ $m^{-2} h^{-1}$ evolved from the sediment in order to maintain the gradient. The profiles from stations at the New York sewage sludge dump (1504, Fig. 1) and the Hudson Shelf trough had higher bottom gradients. Oxygen demand there at a temperature of 13 °C was 43 ml O_2 $m^{-2} h^{-1}$ (ref. 17), equivalent to a regeneration of 126 μg-atom N $m^{-2} h^{-1}$. The low ammonia concentrations off the continental shelf (Station 1512, Fig. 2) are evidence that the high concentrations of ammonia on the bottom of the shelf did not arise from advection from deep offshore water. Because an intense thermocline existed when these samples were taken,

the ammonia could not have come from Hudson River effluent, because that water would have remained mostly near the surface. The high ammonia content must therefore have come from regeneration on or near the bottom.

We can assess the significance of this recycling in two ways. The area of the New York Bight (about 1.17×10^{10} m^2) would recycle 16.8×10^{11} µg-atom NH_4^+ h^{-1}, if our estimated flux of 144 µg-atom NH_4^+ m^{-2} h^{-1} is correct. On the other hand, the Hudson River and Raritan estuary contribute 8.6×10^{10} µg-atom h^{-1}, if one assumes that the net contribution of freshwater, averaged over one year, is 2.4×10^9 l hr^{-1} (ref. 19), and that the average ammonia concentration for the river water is 35.97 µg-atom NH_4^+ l^{-1} (N. Corwin, unpublished). Another important comparison concerns the nitrogen requirements for photosynthesis. The average primary production rate for Stations 1502, 1503, 1509, 1510 and 1511 (Fig. 2) was 0.150 g C m^{-2} d^{-1} (N. Corwin, unpublished), and if the nitrogen used was about 15% of this, the nitrogen requirement for photosynthesis was 67 µg-atom m^{-2} h^{-1}. Based on our estimate (144 µg-atom m^{-2} h^{-1}), bottom regeneration at the time the data were taken could be supplying more than the total required nitrogen. If there were no contribution from the bottom sediments the system would lose this feedback and the production of plant biomass, dependent only on water column regeneration, would be reduced to rates similar to those found beyond the continental shelf.

Fig. 2 Locations of hydrographic stations shown on Fig. 1. Dashed lines parallel to shore are 100 and 1,000 fathom isobaths.

Chemical alkylation of lead

FOLLOWING the reported methylation of lead by anaerobic microorganisms[1] we have investigated organolead compounds in aqueous systems. Our results indicate the possible existence of chemical mechanism for the conversion of trimethyl lead acetate, Me_3PbOAc, to tetramethyl lead (TML) in active anaerobic sediments.

Two basic systems were studied. A 'sulphide' system comprising sodium sulphide (hydrated, 15 mg) in distilled water (200 ml) and a 'sediment' system comprising an anaerobic lake sediment (50 ml), a nutrient broth (CM1), (1 g) and glucose (0.2 g) made up to 200 ml with distilled water. All of the systems were sealed by Subaseals in 250 ml volumetric flasks and stored in the dark. The atmosphere above the solutions was sampled by a syringe and tested for tetraalkyl leads by direct injection into a gas liquid chromatography column coupled to an electron capture detector. The identities of the tetraalkyl leads produced were ascertained by comparsion of their retention times with those of authentic samples.

The addition of Me_3PbOAc (15 mg) to a sediment system produced detectable amounts of TML in the atmosphere above the solution after 1 d and the concentration built up gradually to $6 \mu g\ ml^{-1}$ over two weeks. This gives an approximate figure of 300 μg for the total TML in the atmosphere, which compares favourably with the previously reported figures[1] (125 μg after one week and 642 μg after two weeks), considering the unknown amount of TML absorbed in the solution and on to the walls of the vessel.

The addition of Me_3PbOAc (15 mg) to a sulphide system produced TML within 30 min and the concentration built up to $0.5\ \mu g\ ml^{-1}$ in 7 h and $6\ \mu g\ ml^{-1}$ in 2 d. The addition of Me_3PbOAc to distilled water with no added sulphide gave a constant background level of TML of $0.01\ \mu g\ ml^{-1}$. Substitution of trimethyl lead chloride (Me_3PbCl) for Me_3PbOAc gave identical results.

The addition of 15 mg of triethyl lead chloride (Et_3PbCl) to a sediment system produced tetraethyl lead (TEL) in the atmosphere above the solution. This was detectable after 4 d at a concentration of $0.003\ \mu g\ ml^{-1}$. In this time no methyltriethyl lead ($MeEt_3Pb$) was detected. The addition of Et_3PbCl to a sulphide system produced TEL to a concentration of $0.016\ \mu g\ ml^{-1}$ in 4 d. A solution of Et_3PbCl (15 mg) in distilled water (200 ml) produced no detectable TEL in the atmosphere above it.

A sediment system to which no lead had been added produced no detectable tetraalkyl leads. We were also unable to detect any TML from the addition of lead nitrate ($Pb(NO_3)_2$) to sediment systems.

These results suggest that the main reaction producing tetraalkyl lead from trialkyl lead salts in anaerobic systems is the conversion of the trialkyl lead salt to the sulphide, and the subsequent decomposition of the trialkyl lead sulphide $(R_3Pb)_2S$ to form the tetraalkyl lead. The absence of Et_3MePb when Et_3PbCl is added to sediment shows that no direct methylation is occurring in this case.

Sulphide, in the form of hydrogen sulphide is liberated by many organisms under anaerobic conditions. This would normally react with any metallic ions present to form insoluble sulphides (such as, ferrous sulphide) but, presumably, the trialkyl lead salts compete with these inorganic ions for the sulphide. An earlier report[1] stated that no TML was produced after autoclaving of the sediment; in such a system, the amount of free sulphide available will be low because of the reaction of any H_2S present to form insoluble sulphides, and further H_2S will not be made available for the trialkyl lead salt because of lack of biological acitivity. Thus, if the mechanism proposed here is correct, production of TML from Me_3PbOAc would not be expected to proceed after autoclaving of the sediment.

Furthermore, we have shown that one of the major routes in the methylation of mercury in biological systems is not available to these lead compounds. Following the method of Bertilsson and Neujahr[2] for the methylation of inorganic mercury by methylcobalamin, we substituted equimolar quantities of Me_3PbOAc, Me_3PbCl, Me_2PbCl_2 and $Pb(NO_3)_2$ for the inorganic mercury. In none of these cases did methylation occur.

We propose, therefore, that a possible mechanism for the production of TML from Me_3PbOAc in anaerobic systems is the initial formation of $(Me_3Pb)_2S$ followed by decomposition to give TML as one product. This mechanism seems to be dominant in the reaction of Et_3PbCl in anaerobic conditions to form TEL.

Accuracy of dates beyond the ^{14}C dating limit using the aspartic acid racemisation reaction

RECENT evidence suggests that the racemisation reaction of aspartic acid can be used to date fossil bones[1–3] (for a general review, see ref. 4). At 20 °C, the half life for aspartic acid racemisation is about 15,000 yr. Because the aspartic acid reaction has a longer half life than radiocarbon, it can be used to date bones which are beyond the ^{14}C dating limit (that is, >40,000 yr old). Also, only a few grams of bone are required for a DL-aspartic acid determination, so bones which are available in insufficient quantities for radiocarbon dating can be dated from the extent of aspartic acid racemisation.

The technique is best applied by 'calibrating' the rate of racemisation reaction, using the extent of racemisation in a bone which has been dated by radiocarbon[1–3]. Once this calibration has been carried out for a particular site, then other bones from the site can be dated based on the extent of their racemisation. Ages deduced using this technique have been shown to be in close agreement with radiocarbon ages[1–3].

It is assumed when using this calibration procedure that the average temperature experienced by the calibration sample is approximately the same as that experienced by the sample which is being dated; a 1° difference in average temperature causes about a 20% change in the racemisation rate constant. Although this equal temperature assumption is certainly valid when the ages of the calibration and dated samples are nearly the same, there is a question of whether it is true when the sample age is much greater than that of the calibration sample. Previous results have suggested that a bone which has a radiocarbon age of about 18,000–20,000 yr is a suitable calibration sample for dating older bones[1–3], particularly those too old for ^{14}C dating. In this paper, we have determined the aspartic acid racemisation ages of several bones which are too old for radiocarbon dating. The aspartic acid ages were deduced using a bone about 17,000 yr old as a calibration sample. The ages derived using racemisation are in very close agreement with the ages deduced from other evidence.

The bone samples used in this study came from the Nelson Bay[5] and Klasies River Mouth (KRM) caves in Southern Cape Province, South Africa (ref. 6 and R. Singer and J. J. Wymer, unpublished). The KRM caves contain a long sequence of Middle Stone Age horizons. Radiocarbon dates[7,8] for various South African sites, including the KRM caves themselves, indicate that the end of the Middle Stone Age lies near or beyond the dating limit of radiocarbon (that is, greater than 35,000 or 40,000 yr).

The extent of racemisation of aspartic acid in the bones was determined using the procedures described elsewhere[1]; in general, about 5–10 g bone was processed. The DL-aspartic acid ratios and their corresponding ages, the stratigraphic

Table 1 Aspartic acid racemisation results for Nelson Bay and KRM caves

§Determined on associated charcoal.

¶Determined on associated ostrich eggshell.

‖The radiocarbon results for these levels are discussed and listed by Klein[8].

relationship of the samples, and the radiocarbon dates are summarised in Table 1.

The geological evaluation of the KRM cave I profile (K. W. Butzer, personal communication), oxygen isotopic analysis of marine mollusc shells from the relevant KRM levels (N. J. Shackleton, personal communication), and Klein's faunal studies[8], strongly suggest that the bulk of the KRM cave I Middle Stone Age sequence was deposited during the last interglacial period. The KRM cave I sequence begins on a raised beach which is 6–8 m above the present sea level (ref. 6 and R. Singer and J. J. Wymer, unpublished). The radiometric dating of fossil corals on Oahu, Hawaii[9], and elsewhere[10–12] has indicated that the last time the level of the sea was appreciably higher than it is today was 120,000 yr b.p. This age must represent the maximum age for the KRM cave I deposit, and is in close agreement with the age of 110,000 yr deduced from the extent of aspartic acid racemisation in bones from the lowest occupational horizon at KRM cave I (that is, unit 19).

The Middle Stone Age sequence at the KRM caves contains marine food refuse including seals, birds, fish and shellfish[8]. This indicates that in the time interval during which Middle Stone Age people occupied the caves, the sea was never very far away. (At present, the cave is 10–15 m from the sea.) Following the high sea level stand of 120,000 yr ago, there was a fairly long interval (about 40,000–60,000 yr) of oscillating sea level[12–16]. Periods when the level of the sea was close to but slightly lower than present levels have been dated[12–15] at about 105,000 and about 85,000 yr b.p.; during the intervening periods sea level was significantly lower than it is today[15,16]. These latter high sea level periods coincide extremely well with the ages deduced for the middle and lower Middle Stone Age occupational horizons (that is, units 16, 18, and 19) at KRM cave I.

Klein[8] states that there is a decrease in the relative proportion of seal and marine bird remains in the youngest Middle Stone Age levels of the KRM caves, including unit 13 of KRM cave I. Following this faunal transition period, the cave was abandoned by Middle Stone Age people and remained uninhabited until about 6,000 yr ago. Klein suggests that this occupational gap coincides with the period of essentially permanent depressed sea level during the height of the last glacial age. Sea level curves given by various workers[13–16] indicate that this period of low sea level began about 60,000–70,000 yr b.p. The aspartic acid racemisation age of 65,000 yr for unit 13 at KRM cave I thus also agrees well with the age range estimated from the faunal and archaeological evidence.

We believe that these results provide convincing evidence that the aspartic acid racemisation can be used to deduce accurate ages of fossil bone which are beyond the dating limit of radiocarbon.

We thank R. Klein for supplying the bone material, for reprints of appropriate papers, and for reviewing the manuscript. This work was supported by a grant from the National Science Foundation.

Male transfer in olive baboons

STUDIES of human populations have shown that inbreeding results in an increase in the number of offspring with greatly reduced viability. It seems likely that there are similar effects in other primates. In *Papio anubis* it seems that this problem is reduced by the transfer of males between groups. In a population studied at Gombe National Park in western Tanzania, inbreeding may be essentially avoided through the transfer of all males out of their natal troop.

Since 1967, 41 individuals are known to have transferred in or out of three study troops at Gombe. Thirty-nine of these were males, the other two were an adult female and her juvenile daughter. Of the 39 transferring males, two were juveniles at the time of transfer, four were old adults (with worn canines) at their first observed transfer, and the remaining 33 were subadult or mature adults. Of the 18 adult males that currently reside in the three study troops, 13 are known to have transferred in from outside that troop; the other five are all old and could have transferred before research at Gombe began.

In two of the troops, demographic data has been maintained constantly since October 1967, in the third since January 1970. This work was begun by T. Ransom and subsequently continued by L. Taylor-Nash, N. Owens, and A. Sindamwo. Of the 20 oldest subadult males that were members of the study troops when individuals of those troops were first recognised, 15 are known to have transferred, two disappeared, and three died. None have remained in their natal troops. These 15 transfers all left between the ages of approximately 6–8 years; puberty begins at about 5–5½ years and full size is reached at 6½–7½. Although adults which have not yet transferred may attain a high dominance status among mature males, they consistently rank lowest in time spent consorting oestrous females.

Exchange of males at Gombe involves seven different troops. All transfers have been between troops with adjacent ranges. Six males are known to have transferred more than once. Two of these came back to their natal troop, then returned to the transfer troop. The other four are known to have been members of three troops, while one of these is believed to have been a member of four different troops. Three other males are also believed to have transferred more than once, while all the older migrating individuals may have already switched before their initially observed transfer.

Of the males that have reached maturity since 1967, none has remained in his natal troop. Although it is possible for a female to transfer, it is highly unusual. It seems that every male transfers at some time during his life, most likely spending his reproductive life in a troop other than his natal troop. This phenomenon is still being studied in detail.

Evolutionary trends in the Indian *Iseilema*

OF the most highly evolved grasses, the most useful to man are chiefly confined to the tropical and the warm temperate regions. For example, the Andropogoneae are extensively cultivated for cereals (*Sorghum* spp.), sugar cane (*Saccharum* spp.), essential oils (*Cymbopogon* spp.), and a variety of other purposes. They have attained high adaptive peaks of evolution and species differentiation in the Indo–Malaysian region[1], where there is a high or moderately high rainfall. Three species of the Indian grass *Iseilema* are cultivated for fodder, each one of which is a 'species complex' or a cluster of chromosome races, not randomly united but formed by the genetic system of the taxonomic species. All three complexes show a gradually ascending series of haploid chromosome numbers from 3 to 18 (Table 1), and even the polyploid numbers form an 'aneuploid' series within a complex. Selection, environment, polyploidy and B chromosomes have had varying roles in the evolution of these complexes, and their most notable characteristic is that they form a self-consistent system of evolutionary mechanisms. Here, I demonstrate how *Iseilema* is indicative of the ancient dibasic polyploidy in its tribe, of which it is the highest evolved member; in a habitat where the tribe shows maximum diversity and closest adaptation.

The higher chromosome numbers (Table 1) of *I. laxum* and *I. prostratum* are probably derived from a lower number or numbers by way of remote amphiploidy. For instance, the haploid numbers 14, 14+1B, 15 and 18 of *I. laxum* can all be traced back in a reticulate manner to four secondary basic numbers such as $x_2=6$, 7, 9 and 10 and the latter in turn can be deduced from $n=3$, 4, and 5 of *I. anthephoroides*. The ancient diploid ($n=4$) that is still lingering in the species complex of *I. laxum* lends support to such a view. Hooker[3] stated that *I. anthephoroides* is "nearly allied to *I. laxum*".

* Pending a careful biosystematic study to validate the taxonomic characters such as sterility and variation in the relative lengths of the spikelets[16], sometimes caused respectively by B chromosomes and polygenes, Hooker's species[3] are still maintained.

In spite of many cycles of polyploidy (the highest known to date in the genus), some plants of *I. laxum* ($n=14$) have one B chromosome, and seem to have been selected and retained within the complex, whereas others, with $n=15$ and 18, do not. The B chromosome may play a role in restoring vigour, presumably lost as a result of functional diploidy in these lower polyploids; such a source of vigour, as alternative to polyploidy, is no longer required when the basic number increases and hence the higher polyploids tend to eliminate B chromosomes in *I. laxum*.

I. anthephoroides, however, shows an imposing array of as many as eight different chromosome numbers with one B chromosome at each stage, the presence or absence of which does not affect the chiasma frequency at metaphase I in pollen mother cells. Here, selection is progressing not in favour of an increase but towards constancy in the number of B chromosomes, resulting in balanced polymorphism. In this continuous series of chromosome numbers there is at the moment no way of predicting which, if any, is the most primitive. This difficulty is further enhanced by the fact that several basic numbers have been proposed for the Andropogoneae[9]. If statistics alone can provide an unequivocal answer, then $x=5$, the most frequent number, is an important evolutionary radiation in the Andropogoneae and the same set of five chromosomes is also basic for *Iseilema*. At one time, the Andropogoneae were probably in a state of great flux, centred round a basic set of five chromosomes, from which not only several genera like *Iseilema* but even the highest evolved Maydeae seem to have originated.

Themeda, considered to be phylogenetically related to *Iseilema* (Hubbard and Bor, personal communication), is also based on $x=5$ (refs. 10 and 11). *Themeda* and *Iseilema* may have had a common ancestor with five basic chromosomes. Further, the supposed $x=5$ of *Iseilema* need not be derived from $n=10$, encountered in *I. prostratum* and in other Andropogoneae, through such numbers as $x=9$ and $x=7$ also found in *I. laxum* and *I. prostratum*, because $x=9$ and $x=7$ are in themselves amphiploid and can easily be derived from the $n=3$, 4 and 5 of *I. anthephoroides*; similarly, with $n=6$ which co-exists with the $n=3$.

If $x=n=5$ is accepted as a working hypothesis, the haploid number $n=3$ in *I. anthephoroides* can be derived directly or indirectly from $x=5$ by a progressive and stepwise reduction in the basic number (for example, *Airopsis tenella*[12]), also providing desirable centromere economy. Such a chromosome reduction seems to have gone on unobtrusively in such tribes as Aveneae, Stipeae and Agrosteae in parallel and independent lines but not to the extreme extent found in the Andropogoneae. Parallel chromosome reduction in these grass tribes may be indicative of their genetical relationship and common inheritance from the ancestral grass stock, which has emerged[13] from the Liliaceous stock through Juncales by the process of extreme reduction. Thus, instead of being merely a basic number[5], $n=3$ of *I. anthephoroides* represents a highly advanced number, perhaps the culmination in the tropical Andropogoneae.

What is remarkable in *I.anthephoroides* is not the stringent centromere economy as a measure of achieving the long range advantage in evolution, but the acquisition of B chromosomes to compensate for a decrease in the number of normal chromosomes. It may well be that a reduction to such a low number as 3, the lowest known to date in grasses, has become an evolutionary possibility resulting from the material properties of B chromosomes, which probably belong to an ancient lineage. In other words, the B chromosomes seem to act as buffers to the haploid chromosomes and provide a mechanism for an elastic adjustment of the increased nucleic acid metabolism, as demanded by the evolutionary changes, both within and outside the species.

It is clear that *I.anthephoroides* has achieved internal stability by an extreme reduction in the haploid number to 3 and plasticity by still retaining excessive variability in the haploid number from 3 to 6, with one B chromosome at each stage. These are two conflicting but delicately balanced evolutionary needs which seem to be advantageous to the species. It is in fact a compromise imposed by selection.

What do we learn when the chromosomal evolution in *Iseilema* is related to its geographic distribution? With all the advantages that a balanced polymorphism can confer on a species population, *I.anthephoroides* is still confined to the southern Deccan Peninsula. This may be caused by the fact that, along with increasing specialisation, the species has become adapted to a particular set of environmental conditions obtained only in that area; or the B chromosomes have adaptive properties of their own restricting the species to its present range of distribution (for example, *Clarkia lingulata*)[14]. In contrast, the species complex of *I.laxum* has combined polyploidy and one B chromosome with adaptability, although its area is not commensurate with the high degree of its ploidy, indicating that at least some of its chromosome sets are probably not qualitatively very different from each other. It is distributed over the entire Deccan Peninsula and in Ceylon with a peripheral distribution of its sole diploid ($n=4$) in the Assam area. The geographic distribution of *I.prostratum*, is far wider, covering all parts of India and extending into Burma. Its success cannot be attributed to polyploidy alone, which is not even as high as that of *I.laxum*, but presumably to the onset of a favourable recombination through hybridisation of genetic types, adapted to diverse habitat conditions, such as those in the black cotton soils of Bundelkhand and the moist localities of the Carnatic. Relatively, therefore, it is not the step-wise reduction, but the origin of secondary basic numbers through amphiploidy, that has decided the areas of the Indian species of *Iseilema*. Their ultimate adaptation to specialised habitat conditions within the areas result from intraspecific genetic variation within the complex.

The Andropogoneae have attained a high development in the Indo–Malaysian region, with two zones of maximum species abundance, one in India (the Western Ghats, Bombay Deccan, Madhya Pradesh) and the other in Southern Indonesia (the Lesser Sunda Islands)[1]. It is in this Indian zone of strong species preponderance, that *Iseilema* shows maximum cytological variability with unusually low chromosome numbers, providing a 'pool of chromosome sets', from which the higher chromosome numbers have been derived mostly by amphiploidy and to some extent by autopolyploidy.

Such amphiploidy, involving any two parents with $n=3$, 4 or 5 and leading to the origin of secondary, tertiary and other complex basic numbers, explains the wide gamut of seemingly conflicting basic numbers, such as 5, 6, 7, 9, 10, 11, 12, 14, 15, 17, 18 and 19 encountered in the tribe Andropogoneae of the Indo–Malaysian region[9]. Perhaps it is the differential elimination of certain unsuitable types with $x=8$, 13 and 16 that has created gaps in this otherwise continuous series. It seems that all the basic numbers 3, 4 and 5 were present in the primitive flux of the Andropogoneae making the dibasic polyploidy and the evolution possible in the moist habitats of the Indo–Malaysian region, Hartley's ideas[1] being vindicated. The cytology of the Indian *Iseilema* thus puts the whole tribe Andropogoneae in its proper perspective both in regard to the long range chromosome reduction and the short range polyploidy, and takes us to the very root of Poaceae which, according to some cytologists, is characterised by a basic set of five chromosomes. In other words, the cytology of *Iseilema* illustrates the great series of chromosome changes which the tribe Andropogoneae has undergone since its early divergence from the original grass stock.

I thank Dr C. E. Hubbard, Royal Botanic Gardens, UK, and Professor Arne Müntzing, Institute of Genetics, Lund, Sweden for their interest.

Genetic relationships between brooding and brooded *Actinia tenebrosa*

SEA anemones of the genus *Actinia* seem to be dioecious and reproduce sexually, yet males, females, and individuals without gonads brood juveniles for much of the year[1–3]. How this occurs is still not understood and knowledge on the subject is scant. Gillespie[4] considered that eggs develop to ciliated blastulae and then directly into "a cylindrical form . . . which develops tentacular buds". Chia and Rostron[3] found no pre-planula larval stages in the coelenterons of hundreds of specimens they examined and postulated that most embryos must leave the mother as morulae or blastulae and later resettle in the coelenteric cavities of other adult *A. equina* where they metamorphose to post-Edwardsia juveniles. According to this hypothesis, juveniles contained in an adult should be derived from a number of different parents and would be expected to show a range of phenotypes characteristic of the population rather than the brooding adult. Cain[5], however, found that in phenotypically varied populations of *A. equina*, young anemones invariably had the same colour as the adult from which they were released. He considered it likely that *A. equina* is a protandric hermaphrodite which mainly

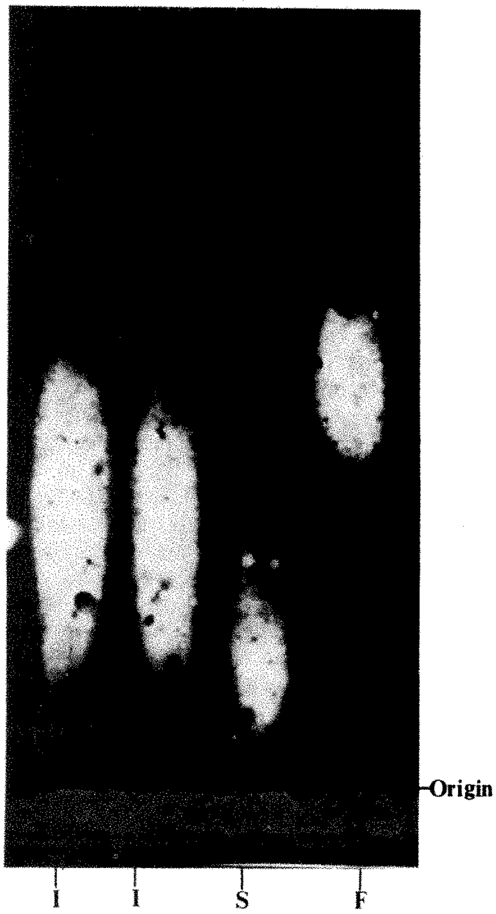

Fig. 1 Starch gel electrophoresis of *A. tenebrosa* catalase in 0.045 M Tris, 0.0008 M Na_2 EDTA, 0.025 M H_3BO_3, *p*H 8.6 buffer. Catalase stain modified from Shaw and Prasad[8]. I, intermediate phenotype; F, fast pheonotype; S, slow phenotype. Samples were frozen, ground in an equal volume of distilled water and centrifuged at 2,000*g*.

self-fertilises and retains larvae within the parent, even though Carlgren[2] thought this "hardly probable".

The intertidal anemone *A. tenebrosa* Farquhar is common on the shores of New Zealand and temperate regions of Australia. There is only one recorded colour phenotype[6], so we examined *A. tenebrosa* for isozyme polymorphisms, similar to those known in *A. equina*[7], to test Chia and Rostron's[3] hypothesis.

Homogenised sea anemone tissue extracts were examined for eight enzymes[8] using starch and gradient acrylamide ('Gradipore') electrophoresis. No traces of peroxidase or leucine aminopeptidase activity were found; there was no individual variation in soluble protein, esterase, acid phosphatase, alkaline phosphatase, alanyl aminopeptidase, or malate dehydrogenase. Three catalase phenotypes were found; fast, intermediate and slow (Fig. 1). From earlier studies of catalase isozyme polymorphisms[9,10] we assumed that *Actinia* catalase is a tetrameric molecule; thus the fast and slow phenotypes were assumed to be homozygotes, whereas the intermediate phenotype was a heterozygote of 'fast' and 'slow' alleles. The intermediate phenotype of *Actinia* catalase should therefore contain five isozyme bands, but these were not distinguishable on our gels.

The sea anemones were collected from four localities near Adelaide, South Australia (Table 1). Phenotype frequencies varied between localities and in the Outer Harbour sample there was a highly significant excess of putative heterozygotes, assuming a diploid diallelic system, with respect to Hardy–Weinberg frequencies. Some large brooded juveniles from the Outer Harbour sample provided sufficient catalase to give a staining reaction after electrophoresis. Phenotypes of 23 juveniles were determined (Table 2). Every juvenile examined had the same catalase phenotype as the host adult.

Table 1 Catalase phenotype frequencies from different localities

Samples	Phenotypes			X test for Hardy–Weinberg frequencies	
	Slow	Intermediate	Fast		
Outer Harbour (Adelaide)	6	59	2	39.46	$P<1\%$
Victor Harbour	0	3	9	—	—
Talisker Mines Beach (Cape Jervis)	0	5	5	—	—
Pennington Bay (Kangaroo Island)	16	5	0	0.38	—

Our results are therefore consistent with those of Cain[5], but we feel that the information available is insufficient and too contradictory to allow detailed speculation on the nature of the breeding system in *Actinia*. The correlation between phenotypes of adults and their brooded juveniles could indicate either asexual reproduction or apomictic parthenogenesis, but these systems would be inconsistent with previous observations of apparently functional male and female gonads. Furthermore, recent work raises an unlikely possibility that has not been dismissed: that a brooding adult may differentiate genotypes of brooded juveniles and reject those incompatible with its own.

Table 2 Phenotypes of juveniles extracted from adult *A. tenebrosa* in the Outer Harbour sample

Catalase phenotype of juveniles	Catalase phenotypes of nurse adults		
	Slow	Intermediate	Fast
Slow	5	0	0
Intermediate	0	15	0
Fast	0	0	3

Francis[11] showed that *Anthopleura elegantissima* distinguished between contacts of clonemates (of like genotype) and non-clonemates (of unlike genotypes), and reacted aggressively to the latter. *Actinia* also exhibits intraspecific conflicts[12], which may result in death of a juvenile involved in an adult–juvenile encounter (J. R. O., unpublished). Successfully brooded juveniles could therefore be only those genetically similar to the host, regardless of whether they resulted from cross-fertilisation of one or many matings. One approach to resolve this problem would be to breed adult *Actinia* in captivity for several years and compare fecundity of animals in solitary and group isolation with similar individuals and groups that were not isolated but had access to planulae from the sea.

Finally, we comment on Cain's assumption that *A. equina* is "so long lived". Substantial longevity data are available for only four species of sea anemones, all of which are for captive animals[13–16]. Only two of these records are for *A. equina*: one of Dalyell's specimens lived about 66 yr[14] and another lived 14 yr[13], but the lifespan of animals in such conditions may far exceed "ecological longevity" since a captive animal is usually protected from predators, hazards of the environment and scarcity of food[17]. Thus, although some actinians may have the potential to live many decades, it is possibly quite a rare occurrence in nature.

This study was supported by Dr F. Jacka, Director, Mawson Institute for Antarctic Research, and by a

University of Adelaide Research Grant Scholarship to G. C. K. during 1971–72.

Epidermal mucus and the reproduction of a crinoid echinoderm

THE unstalked crinoid *Comanthus japonica* spawns during the first part of October each year[1,2]. For a study of gametogenesis[2], specimens of *Comanthus* were collected periodically over 14 months. During these collections, one of us (J. G.) noticed that the animals became unusually slimy to the touch during the six to eight weeks that preceded spawning. This transient slimyness is correlated with an enlargement of an epidermal mucous cell population. The general position of the mucous cells is shown in Fig. 1, in which they are darkly stained. In both male and female genital pinnules, these cells occur mostly in the oral and lateral body wall. Each individual mucus cell is oval and contains a single nucleus. The cytoplasm stains with beta- to gamma-metachromasia in azure A. In addition, the cytoplasm stains strongly with alcian blue at *p*H 3, but fails to stain with periodic acid–Schiff. These histochemical criteria indicate an abundance of sulphated acid mucopolysaccharides (possibly mixed with non-sulphated acid mucopolysaccharides). It is not known if similar mucous cells occur in the arms and central mass of the crinoids, since these body regions were not preserved for histology.

In both sexes, the volume of the epidermal mucous cell population increases conspicuously in the weeks before spawning (Fig. 2). In the female (Fig. 2*a*), this increase is about ten times as great as in the male (Fig. 2*b*). The volume of the mucous cell population decreases markedly around the time of spawning in October in the female, but not in the male. Instead, the volume in the male declines gradually during the autumn and winter.

In both males and females, the population volume of the mucous cells increases abruptly in August. Therefore, the increase might be elicited in both sexes by the same environmental signal. The much greater increase in females could result from endocrinological differences between males and females; or there might simply be more mucous cells (or their precursors) in females. At present, it is not known if mucous cells are derived from or give rise to other cell types in adult crinoids. There is certainly no morphological evidence that the mucous cells are related to the so-called dorsal glands[4] of the body wall.

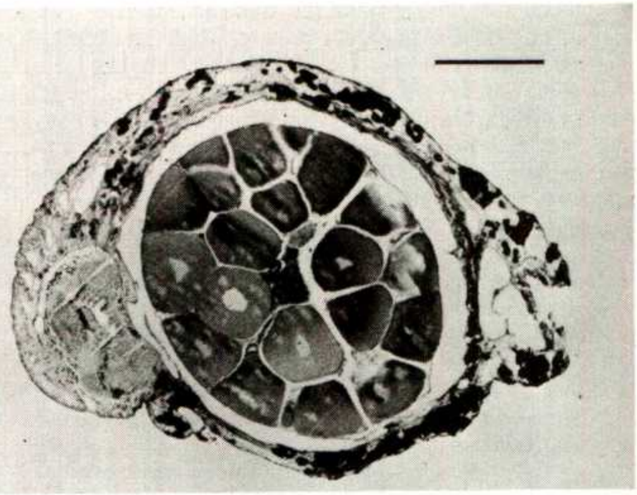

Fig. 1 Cross section of a genital pinnule from a female specimen of *Comanthus japonica* collected on September 15, 1973. The oral side with the food groove is at the right and the aboral side with the pinnular ossicle is at the left. The ovary, containing conspicuous oocytes, is separated from extragonadal portions of the pinnule by a genital coelom. Fixation was on the day of collection in seawater–Bouin's fluid. Staining[3] was in alcian blue at *p*H 3. The epidermal mucous cells are the darkly stained objects in the oral and lateral body wall. The scale line represents 250 μm.

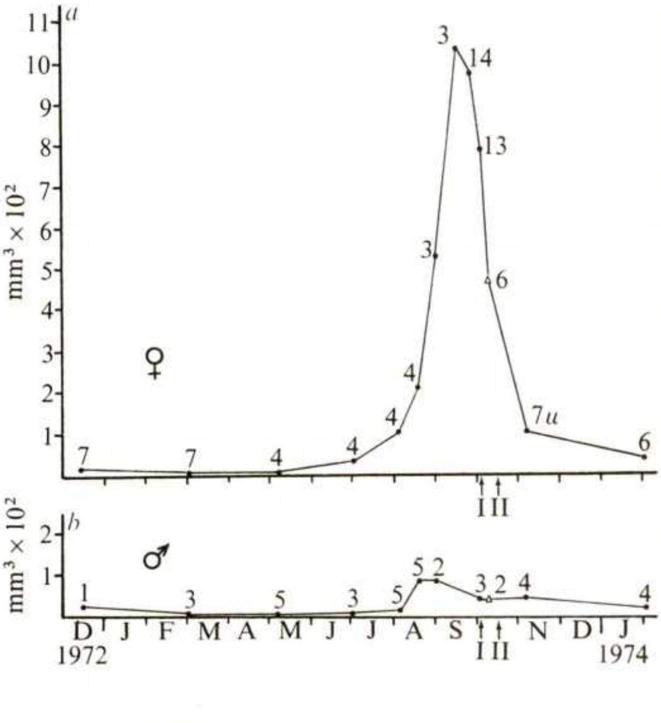
The marked fluctuations in the size of the mucous cell populations around the time of spawning indicate that the epidermal mucus has some function in the reproductive biology of female crinoids. It is possible that the release of much epidermal mucus into the seawater by spawning females may act as a pheromone to stimulate epidemic spawning in nearby crinoids. Dan and Dan[5] have shown, however, that such a pheromone is not necessary in all cases, since a male crinoid can spawn in isolation from spawning females (and *vice versa*).

Fig. 2 Volume fluctuations of epidermal mucous cell populations in females (*a*) and males (*b*) of *Comanthus japonica*. Volumes, given in $mm^3 \times 10^2$ per genital pinnule, were measured by the method of Holland *et al.*[2]. The number of the individual females or males averaged for each data point is given above each collection date. For the collection of October 7, 1973, (△), only spawned animals were taken into account; the spawnings of the first and third weeks of October 1973 are marked, respectively, by arrows I and II. The November data point marked 'u' on the top graph is for animals which could not be sexed, most or all of which were probably females (see Holland *et al.*[2]).



Another, and more probable, function of the female's epidermal mucus may be to supply a temporary binding material for the newly released eggs. Dan and Dan[5] discovered that the eggs of *Comanthus* are mixed with a viscous binding material which rises slowly through the seawater in a column above the spawning female. It was assumed[5] that this material was produced within the ovary from dissolution of the jelly coats of eggs. But much (perhaps all) of the binding material may be supplied by the epidermal mucous cells. If there is a sudden secretion of a large part of the epidermal mucus at spawning, the epidermal mucous cells may well be responding to the same hormone(s) that presumably direct maturation, ovulation and spawning in this species.

Siphon regeneration in *Ciona*

IN 1923 Paul Kammerer summarised research which he claimed demonstrated the inheritance of acquired characteristics. Since the success of Mendelian genetics had already made Kammerer's work suspect, a report of his lecture[1] was followed by a long and acrimonious debate. The Kammerer case thereby became a *cause célèbre* in the biology of that decade. The controversy has recently been resurrected in a popular book by Koestler[2] and has gained additional prominence from an internationally televised BBC documentary based on the book. This paper reports a failure to duplicate one of Kammerer's key experiments.

One of the examples cited by Kammerer purported to show that environmentally induced nuptial pads on the forelimbs of the male midwife toad, *Alytes obstetricans*, were inherited by the male offspring[3]. In 1926, however, this work was discredited by the finding that the nuptial pads on his one remaining *Alytes* specimen in the museum of the Vienna Institute for Experimental Biology were fraudulent[4]. Although Kammerer protested innocence of the forgery, the disgrace contributed to his suicide shortly afterwards[5].

Koestler has staunchly defended Kammerer's scientific integrity[2], and on the basis of his presumed innocence in the matter of the midwife toad, and on the grounds that Kammerer's experiments were never properly repeated, he urges the scientific community to reinvestigate the work. Although there is ample reason to disagree with Kammerer's (and Koestler's) Lamarckian interpretations[6], some of his experimental observations may nevertheless still be valid.

Kammerer himself believed that his experiments on siphon regeneration in the ascidian *Ciona intestinalis* L. were his best evidence for the inheritance of induced somatic changes[1,7,8], and Koestler particularly seeks a repetition of this work[2]. The original experiment and its results are summarised in Fig. 1. Removal of parts of the incurrent and excurrent siphons (Fig. 1*a*) resulted in more elongated siphons being regenerated, even after a single excision. After a second removal of the newly regenerated siphons, still longer siphons were produced (Fig. 1*b*). The gonads were then made to regenerate by removing a basal segment of the animal containing the ovary and lower part of the intestine (Fig. 1*b* and *c*); Kammerer felt that the regenerating gonads would be more amenable to somatic influences. The F_1 progeny of these gonad-regenerated animals were shown to have elongated siphons (Fig. 1*d*) like the parents.

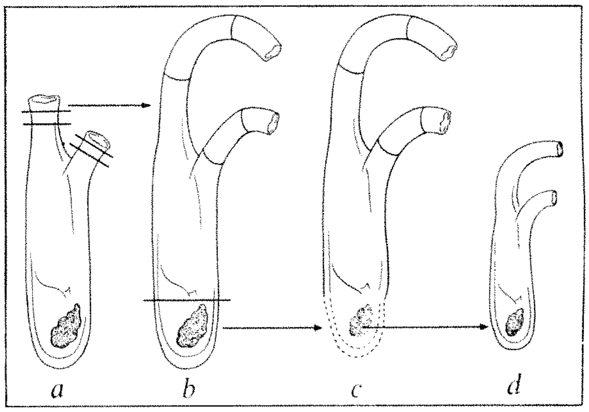

Fig. 1 Diagrammatic representation of the *Ciona* regeneration experiment purportedly done by Kammerer[8]. *a*, Distal halves of the incurrent and excurrent siphons of the animals were excised (cuts indicated by the solid line) and permitted to regenerate twice in succession, to produce animals with exceptionally long siphons as depicted in *b*. Regenerated siphons had a jointed or noded appearance. *b*, Gonad of the long-siphoned *Ciona* made to regenerate by cutting off (solid line) the basal part of the body which contains the gonad. *c*, Long-siphoned animals which had regenerated new basal parts and gonads (shown by dotted lines) were used to provide eggs and sperm for an F_1 generation. *d*, Young *Ciona* (F_1) resulting from this genetic cross were reported to have long siphons like the parents.

In response to Koestler's appeal[2], I attempted to repeat this regeneration experiment during the summer of 1973. Adult *Ciona intestinalis* (8–12 cm long) were kept at Woods Hole in a tank in which the incoming fresh seawater was refrigerated to 12–15 °C. Cionas survive much better in cooler water than in the warmer laboratory sea tables. Before surgical amputations, the animals were anaesthetised with 0.01% tricaine methanesulphonate (MS 222; Sandoz Pharmaceuticals).

Two groups of 50 animals each had both siphons amputated: group 1 had the whole siphon removed at the base, and group 2 had the distal half of each siphon removed. Healing was quite rapid[9] and new ocelli (reddish-orange photoreceptors[10]) appeared on the siphon edges within 4–6 d. Animals of both groups had completely regenerated their siphon lengths by 30–40 d, and showed no indication of siphon elongation nor any sign of a jointed or noded appearance of the siphons[8].

A control group of 50 unoperated animals was kept in the same tank for comparison of relative siphon lengths. Group 1 were kept up to 60 d (38% survived compared with 68% of the control group) without any indication of excessive siphon growth. Likewise, the group 2 animals were kept for 53 d (56% surviving), also without siphon elongations beyond their normal proportions. Since siphon elongation was reported to occur even after a single amputation[8], it seemed pointless to amputate the animals a second time.

These results agree with those of Fox[11], who attempted to repeat the *Ciona* experiments at the time of the original controversy. In addition to Kammerer's report, however, an earlier worker had also described siphon elongations in *Ciona* after a single amputation of the siphons[12]. A suggestion[11] that these positive results could be caused by nutritional conditions which were known to produce elongated siphons in *Ciona*[13], was flatly rejected by Kammerer[14].

No attention seems to have been paid during the controversy[2] to the final phase of Kammerer's experiment in which he claimed to have obtained gonad regeneration. Gonad regeneration occurs in another ascidian, *Clavellina lepadiformis*[15], and recent work shows that *Ciona* will regenerate a new ovary if the original is carefully removed through a small slit in the body wall[16]. Anyone actually trying the final operation depicted in Fig. 1*b* and *c*, however, could not fail to be impressed by the improbability of the animals surviving such trauma. In fact, Hirschler[17], in his extensive study of *Ciona* regeneration, found that animals could not survive this particular operation.

This point was investigated further by subjecting a third group of 50 normal animals to the gonad operation described by Kammerer[8], and as depicted in Fig. 1*b*. All of the animals died between 3 and 6 d after the operation.

The failures of Fox[11] and myself to observe siphon elongation in regenerating *Ciona* suggest that elongation is not a commonplace occurrence and may indeed be caused only by special circumstances[13]. Kammerer's claims must therefore continue to be regarded with scepticism, especially as evidence presented here and elsewhere[17] indicates that *Ciona* does not survive the gonad regeneration operation claimed to have been used by him.

This investigation was supported by a US Public Health Service research grant.

Temperature receptors on tarsi of the tsetse fly *Glossina morsitans* West

ELECTROPHYSIOLOGICAL techniques have shown that the responses of mechano- chemo- and olfactory receptors in insects are temperature-dependent[1-3], and several true thermoreceptors have been described[4-8]. We have found thermosensitive cells on the tarsi of the tsetse fly that seem to be involved in probing behaviour. Electrophysiological recordings revealed spontaneously discharging cells in two hairs on the third, fourth and fifth prothoracic tarsomeres. These hairs are part of two ventrolateral rows of hairs probably similar to the receptors (re) described by Lewis for *Glossina palpalis*[9]. No spontaneously firing cells were found on the meso- or metathoracic legs. Detailed studies were made only on the fifth tarsomere hairs.

Table 1 Probing responses of *G. morsitans*

	n	No. of flies settled on membrane	No. of flies probing	No. probing / No. settled
Post-teneral males				
Accumulated controls	96	90	84	0.93
Antennae removed	43	?	2	
Pro. tarsi removed	61	57	47	0.82
Acetic acid on meso. tarsi	9	8	7	0.79
Acetic acid on pro. tarsi	33	26	3	0.12
Teneral males and females				
Accumulated controls	60	56	54	0.96
Pro. tarsi removed	45	41	26	0.63
Acetic acid on meso. tarsi	32	27	25	0.93
Acetic acid on Pro. tarsi	29	26	6	0.24

Post-teneral males were 1–3 weeks old and had been starved for 48 h. Teneral flies were starved for 24–48 h. Cages containing five to seven flies each were placed for 3 min on a 1-mm thick Agar/Parafilm membrane[13] overlaying a feeding solution (10^{-3} M ATP in 0.15 M NaCl, warmed to 37 °C with *p*H adjusted to 7.0). Glacial acetic acid was applied after the inconclusive results of the tarsalectomy experiments. Electrophysiological experiments had shown that application of the acid to the tip of the hair gives an injury reaction: a burst of spikes followed by inactivity of the temperature receptor. To apply the glacial acetic acid, a glass tube (outer diameter about 1 mm), filled with the chemical, was placed over the leg of the fly. In this way evaporation of the acid, which may cause damage to other receptors, was minimised.

At room temperature, there were usually two cells firing in each hair. One gave large spikes (0.8–1.0 mV) at irregular intervals (on average 1–2 s^{-1}) and the other gave smaller spikes (0.3–0.6 mV) at a frequency of 20–40 s^{-1}. The large spikes gave occasional bursts, which often, though not always, coincided with a change in temperature. Air movement alone did not evoke the bursts, and some occurred without any detectable stimulus. Over a temperature range of 16–32 °C, the cell giving the small spikes showed all the characteristics of a cold receptor as defined by Hensel[10] (Fig. 1). At other temperatures the amplitude of the spikes usually decreased to zero. Below 18 °C the decrease in amplitude was sometimes preceded by a sudden drop in frequency.

A sudden change in temperature caused a phasic increase

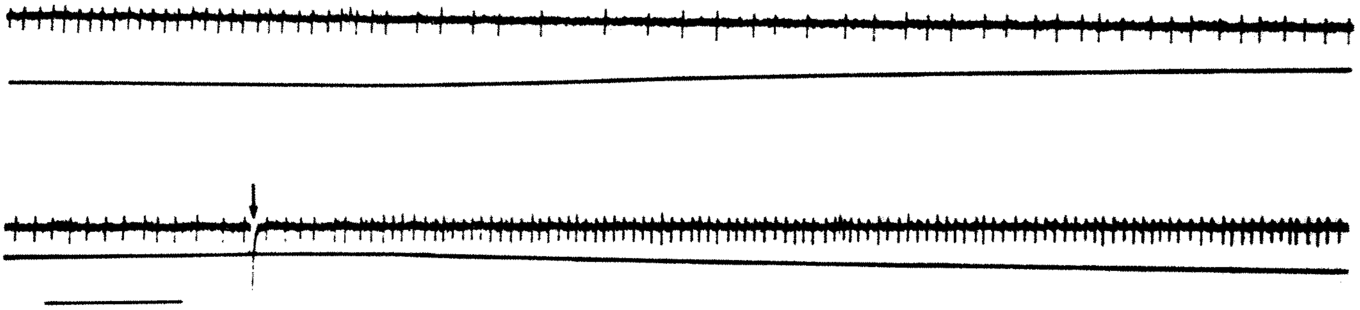

Fig. 1 Record of responses from a hair on the fifth tarsomere containing a cold receptor. The time bar represents 0.25s. The fly's leg was cut off at the base of the tibia and mounted on a glass pipette filled with saline (0.15 M NaCl) which served as the indifferent electrode. Extracellular recordings were made from the tip of the hair by placing a glass pipette (outer diameter of tip 6 μm) containing saline over the hair[11]. A silver wire in the saline passed the signal to a W-P, VF-1 voltage follower, and the output was viewed on a Tektronix oscilloscope. Records were made with a Honeywell 1858 oscillographic recorder or with a Grass C-4 camera. Air at 2–50 °C was blown from a glass condenser over the leg, to obtain an ambient temperature range of 15–35 °C measured with a small (diameter 0.095 inch) epoxy coated thermistor mounted approximately 5 mm from the tip of the hair. The top trace represents the response of the cold receptor to an application of a warm airstream, while the third trace represents the response of the same cell to removal of the warm airstream (arrow and electrical artefact). The recording is continuous. The line under each electrophysiological trace represents the response of the thermistor. The response of the thermistor is not necessarily a true indication of the rate or magnitude of the temperature change at the surface of the receptor. With longer applications than shown here, however, it was possible to get an approximation of the magnitude of the temperature change when the thermistor had stabilised (see Fig. 2*a*).

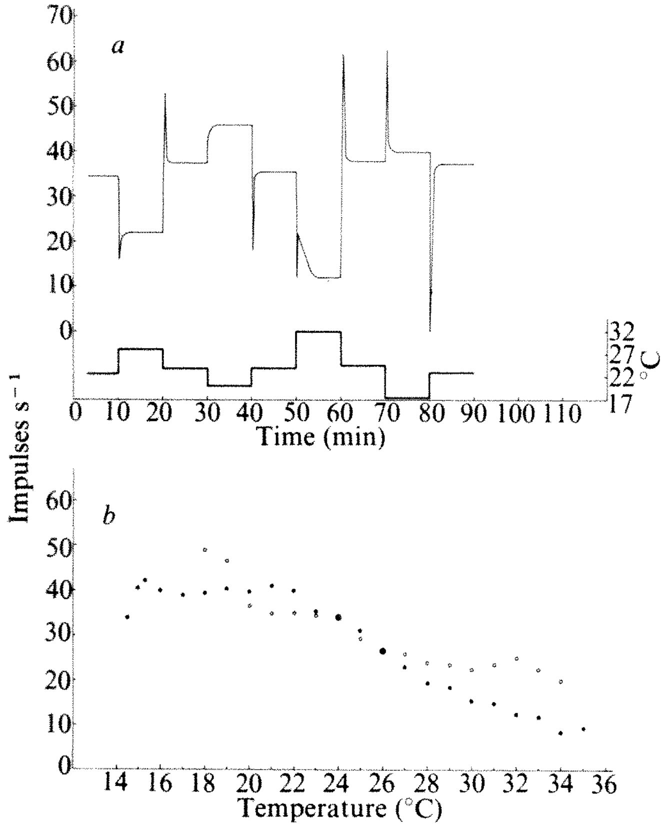

Fig. 2 *a*, Responses of a single cold receptor (top graph) to rapid changes in temperature followed by steady temperatures (bottom graph). The air in the condensor was held at various temperatures (above or below room temperature) and then applied suddenly to the preparation (see Fig. 1). The preparation was held subsequently at each new temperature for 10 min before being returned suddenly to room temperature for 10 min. An approximation of the magnitude of the temperature change was obtained in each case when the thermistor equilibrated. The changes are plotted as instantaneous, and must have been very fast, at the receptor level, judging from its response. *b*, Response of a single cold receptor to slow changes in temperature. The temperature was allowed to increase from about 15 °C to over 34 °C, and the response of the cell was monitored at regular intervals (●). After 169 min, the temperature was decreased, and cell response was again plotted (○) for 64 min.

(cooling) or decrease (warming) of spike frequency, of a size determined both by the extent of the temperature change and by the initial steady temperature (Fig. 2*a*). Frequencies up to 80 spikes per s were recorded in response to a rapid decrease in temperature. When temperature changed slowly (1 °C per 3–5 min), from approximately 21 to 34°C, the firing frequency of the cell followed almost linearly (Q_{10}=0.4–0.7) (Fig. 2*b*). Above 40 spikes per s tonic reactions of the cell became unpredictable.

To test the possibility that the temperature receptor may also respond to chemicals, NaCl (1.0 M), urea (0.1 M) and LiCl (0.3 M) were each applied to the hair. In each case, the temperature receptor functioned normally.

Of what value are these thermosensitive cells to the tsetse fly? Electrophysiological identification of such receptors gives no clue to any influence they may have on the animal's behaviour. Dethier[12] showed that heat is the major stimulus that induces probing, and that the receptors detecting the heat source are on the antennae, rather than on the palpi. Although he mentioned temperature sensitivity of the legs, only chemical responses were studied in detail. When we removed the prothoracic legs, results were variable but there tended to be a reduction in the number of flies which probed. This was easier to demonstrate in teneral flies (newly emerged flies before their first meal) than in post-teneral flies. Treatment of the prothoracic legs with glacial acetic acid eliminated the probing response in most teneral and post-teneral flies (Table 1). In a control group, with mesothoracic legs treated with glacial acetic acid, the probing response was not altered significantly. We conclude that, in its probing response, the tsetse fly uses a secondary input from the temperature receptors on the tarsi, in addition to the primary input from the receptors on the antennae. Why acetic acid treatment disrupted probing more effectively than removal of the prothoracic legs is unknown.

We thank Dr R. H. Gooding for helpful discussions, and for tsetse flies and Dr E. E. Davis of Stanford Research Institute, Menlo Park, California for his unpublished manuscript. This work was supported by the US Army, Medical Research and Development Command, and was carried out while H. R. v H. held a Canada Council Scholarship.

Passive immunisation of marmoset monkeys against neoplasia induced by a herpesvirus

THE malignant lymphoma induced by herpesvirus saimiri (HVS) in non-human primates[1] provides a model system for the study of the prevention of neoplasia in man induced by suspected oncogenic herpesviruses[2]. We have reported that cotton topped (CT) marmoset monkeys (*Saguinus oedipus*) actively immunised with a killed HVS vaccine were resistant to the inoculation of the oncogenic HVS while the non-vaccinated control monkeys died of malignant lymphoma[3]. In certain virus infections (for example, measles, infectious hepatitis, German measles) passive immunisation by administration of specific serum antibodies during the incubation period may result in prevention or modification of the clinical disease. This paper describes the prevention of herpesvirus induced malignant lymphoma in monkeys by passive immunisation.

For all experiments described HVS isolate S.295C[1] was used. The virus was cultivated on owl monkey kidney (OMK) cells[4] and stored at 4 °C as stock virus. For the passive immunisation of CT marmosets whole serum passed through Millipore membrane filters (450 nm) was used. The monkeys received the immune serum by intramuscular inoculation in the lower extremities and were challenged 24 h later by intramuscular inoculation of HVS in an upper extremity. Serial tenfold dilutions of filtered (450 nm) stock virus were prepared for challenge. Aliquots (1 ml) of each dilution were injected into passively immunised monkeys and also into non-immunised control monkeys. The infectivity titre ($TCID_{50}$) of the virus dilutions was determined in parallel in OMK cells.

CT marmosets with HVS induced malignant lymphoma developed high titres of specific serum antibodies against HVS[5]. In the first experiment immune serum obtained from tumour-bearing CT marmosets was used. One of the two immune sera tested was obtained from a CT marmoset that had received 2×10^6 freshly prepared tumour cells derived from an animal of the same species with HVS induced

malignant lymphoma. The recipient CT marmoset died of malignant lymphoma 36 d after the cell transplantation. The serum was taken from this monkey at the time of death. The neutralisation index of this serum determined in OMK cells according to standard techniques[6] was 3.0. The serum (6 ml) was inoculated in a CT marmoset. This monkey was challenged with the 10^{-1} dilution of the stock virus. The TCID$_{50}$ of the 10^{-1} dilution was 1,000 (Table 1) and corresponded to 3,162 LD$_{50}$ calculated according to the method of Reed and Muench (Table 2). The immunised monkey showed delayed tumour development and survived 134 d whereas the non-immunised control monkey died 33 d after inoculation of malignant lymphoma (Table 1). The second immune serum was obtained from four CT marmosets that had been inoculated with 10 TCID$_{50}$ of cell free HVS stock virus. All four monkeys had died of malignant lymphoma 34–42 d after infection. The neutralisation index of the pooled serum from these monkeys was 2.8. Three CT marmosets each received 6 ml from this serum pool. These three monkeys were challenged with the 10^{-3} dilution of the stock virus which contained 10 TCID$_{50}$ of HVS corresponding to 32 LD$_{50}$. While the three non-immunised control monkeys died of malignant lymphoma 23–45 d after inoculation, two of the passively immunised monkeys died of the tumour as late as 73 and 79 d after inoculation and the third of the passively immunised monkeys survived without any sign of a clinical disease or infection with HVS as monitored by cocultivation of its peripheral blood with OMK cells[7]. This animal has now been under observation for 346 d (Table 1).

For the second experiment the serum for the passive immunisation was obtained from CT marmosets actively immunised with a killed HVS vaccine as described previously[8]. None of these monkeys showed signs of a HVS infection[4]. Blood was drawn from 24 vaccinated CT marmosets at different time intervals after the immunisation with the HVS vaccine and the sera were pooled. The neutralisation index of the serum pool was 3.5 and the titre of the complement fixing (CF) antibodies was 1 : 32. The CF titres were determined according to standard techniques[6] using a HVS antiserum from an owl monkey[4]. Six CT marmosets each received 6 ml of this serum. The titres of neutralising serum antibodies in the peripheral blood of these monkeys were determined 24 h later, before challenge. At this time the neutralisation indices ranged from 1.8 to 2.0. After 103 d they had dropped to nearly zero. These monkeys were challenged with the 10^{-1} and 10^{-3} dilutions of the stock virus. Both the passively immunised monkeys that had been

‡Monkey died of malignant lymphoma.
§Monkey is clinically well.

challenged with the 10^{-1} dilution died of malignant lymphoma. The tumours appeared only after a delay, however, and the monkeys died 63 and 74 d after the challenge whereas the non-immunised control monkeys died 28 and 34 d after inoculation (Table 2). All of the four passively immunised monkeys that received the 10^{-3} dilution survived without any sign of disease or virus replication and have now been under observation for 204 d. In contrast, all of the non-immunised monkeys that received the 10^{-3} dilution died 23–47 d after inoculation of malignant lymphoma and even all four of those control monkeys that received the 10^{-4} dilution developed a tumour (Table 2).

These experiments demonstrate clearly that non-human primates can be protected against HVS induced malignant lymphoma by passive immunisation. The passively immunised CT marmoset monkeys were resistant to small dosages of cell-free HVS during an observation period of 204 and 346 d whereas the non-immunised control monkeys died of malignant lymphoma. Challenge with doses higher than 32 LD_{50} of HVS regularly induced a tumour in the passively immunised CT marmosets. The development of malignant lymphoma, however, was considerably delayed in these monkeys as compared with the non-immunised control monkeys. The serum obtained from tumour-bearing CT marmosets protected another CT marmoset against a tumour of the same kind. The fact that the humoral antibodies were not able to stop the growth of an established tumour in the donor of the serum indicates that a passive immunisation may only protect if carried out before the intracellular establishment of the infection. Humoral antibodies do not protect against the cellular transmission of herpesviruses[9] and antibodies against herpes simplex virus types 1 and 2 provide little protection against recurrent disease in man[10]. The active immunisation of CT marmosets with a killed HVS vaccine[8] protected against malignant lymphoma induced by the inoculation of cell free HVS[3]. The fact that the protection could be transmitted with the serum of the vaccinated monkeys indicates that humoral antibodies are important in resistance to HVS in those experiments. In addition, the results obtained with passive immunisation against HVS support the concept that HVS is the aetiological agent for the tumours.

Differential heat response of normal and transformed human cells in tissue culture

MUCH interest has been rekindled in the possible use of hyperthermia either alone or as an adjunct to more conventional treatments in the management of malignant disease. There are several reasons for this renewed interest: data indicate that malignant murine cells may be more sensitive to increased temperature than their normal counterparts[1,2]; temperatures in the range 39–43 °C sensitise cells, and particularly radioresistant hypoxic cells, to X rays[3–6] and to chemotherapeutic agents[7–9]; and humans can stand prolonged exposures to temperatures up to 43 °C, provided adequate supportive precautions are taken[10,11].

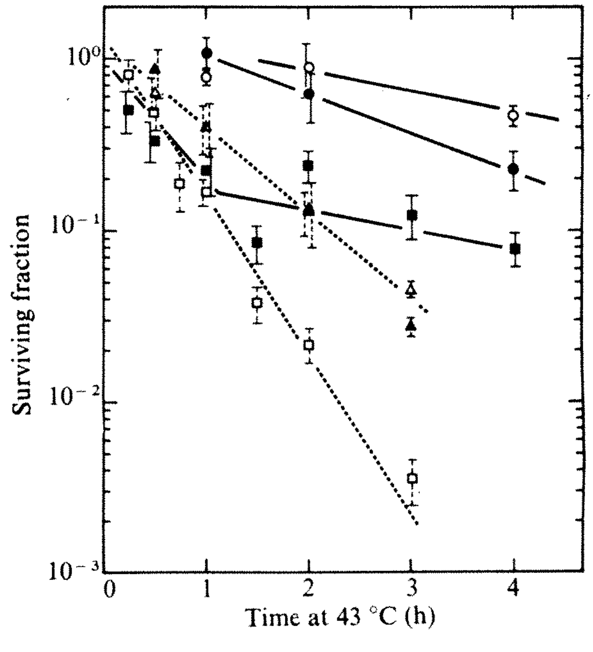
Surprisingly, the literature contains essentially no quantitative data on the thermal response of normal human cells; *a fortiori* there are no data on comparative response of normal cells and similar cells shown to be malignant by implantation into immunodeficient animal hosts. We have therefore initiated such an investigation using the embryonic lung fibroblasts WI-38[12] and SV-40 transformed WI-38-VA13/2RA[13]. Our findings indicate that, indeed, the transformed cells are consistently more sensitive to 43 °C exposures. Furthermore, we show that the kinetics after heat shock of the two cell populations are different, a finding which may have application in sequential heat–X ray or heat–chemotherapy.

Both cell strains were tested for tumorgenicity by injecting 2×10^5–2×10^6 cells subcutaneously into the flanks of homozygotic *nu/nu* mice developed on an NIH background at Stanford Medical Center and maintained under aseptic conditions. One of five mice injected with WI-38-VA13/2RA cells developed a visible nodule within 10 d of injection. None of the three mice injected with WI-38 cells developed nodules. These results are similar to those published elsewhere[14] for other malignant human cells. Furthermore, essentially similar results were shown after implantation of cells of a similar origin as WI-38 and WI-38-VA13 cells into terminal cancer patients[15,16].

The cells were plated in 60 mm plastic Petri dishes at 1×10^5–2×10^5 cells per dish in 5 ml of Eagle's MEM supplemented with 15% foetal calf serum medium. Cells in exponential growth were used on either day 1 or day 2 after plating. The population doubling time in exponential growth varied from 22 to 32 h. Cells reached a confluent monolayer in 9 to 11 d after plating with no change of medium. These plateau-phase cells were used either with no change of medium or with fresh medium applied on the day before heating and again on the day of heating.

Cells were heated by placing replicate dishes in a rack which

Fig. 1 Survival of exponentially growing cells (■, WI-38 and □, 2RA) and plateau-phase cells (●, WI-38, fed; ○, WI-38, unfed; ▲, fed; △, 2RA, unfed) exposed for various times at 43 °C. Unfed cells had no medium change since planting. Fed cells had a medium exchange on the day before and the day of the heat treatment. Error bars represent 1 s.e.m.



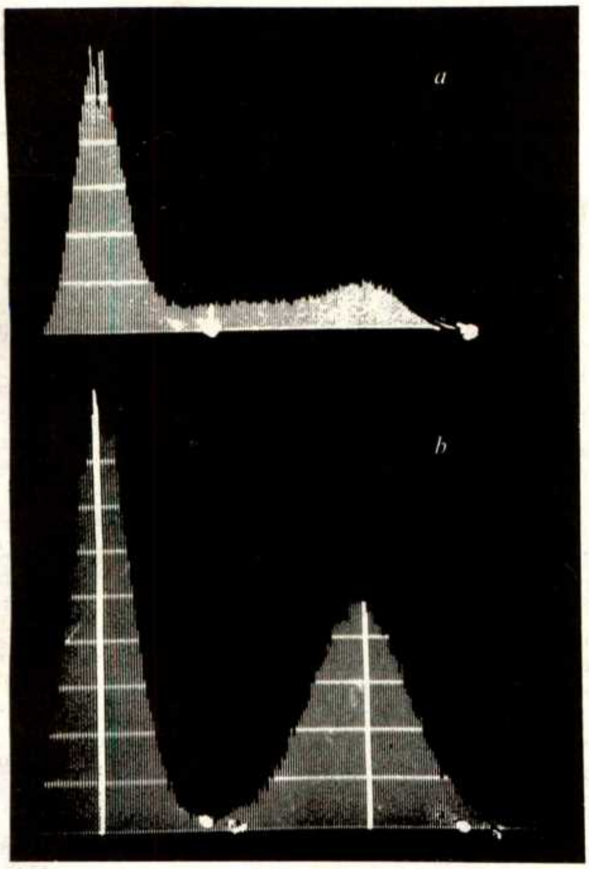


Fig. 2 DNA distributions of WI-38 cells. *a*, Normal distribution of exponentially growing cells; *b*, distribution of cells 24 h after heating at 43 °C for 4 h.

allowed the cells and growth medium to be immersed in a 43 °C water bath. The water bath was inside an incubator and a mixture of air and 5% CO_2 was bubbled through the water constantly. Water temperature was controlled to ±0.1 °C by a proportional controller (Versatherm Model 2156, Cole-Parmer Co.).

For survival experiments, cells were detached after heat treatment using 0.05% trypsin and replanted at the appropriate dilution in 60-mm or 100-mm plastic Petri dishes for cloning at 37 °C. Cloning efficiencies varied from 5% to 35%. Survival results, illustrated in Fig. 1, show that generally the transformed cells exhibited a lower survival than the normal cells when given the same exposure to 43 °C in the same conditions of cell growth, confirming observations with murine cells[1,2]. Fresh medium seems to have had a slight sensitising effect on the normal cells. Also the exponentially growing cells survived less well than plateau-phase cells. This result is contrary to that found with one other mammalian cell line[17].

To determine the effect on cell population kinetics during and after exposure to 43 °C, we studied the changes in the DNA distribution of the cell populations after heating. Several dishes of exponentially growing cells were heated at 43 °C for a fixed time. At various times up to 6 d after heat treatment, replicate dishes were trypsinised and the cells were fixed and stained with ethidium bromide[17]. The cell suspension was then passed through a commercially available fluorescence flow system (Cytofluorograph 4801, BioPhysics Systems, Inc.); output signals from which were accumulated on a multichannel analyser. Since the uptake of dye per cell is directly proportional to DNA content[18], the analyser output is a representation of the DNA distribution of the cell population. Typical distributions are shown in Figs 2 and 3, which also show typical shifts in the distributions after heating. Cells in G1 appear in the first peak while cells in G2-M, with a double DNA complement, appear in the second peak. S-phase cells fall in between the two peaks.

A sample containing equal numbers of each cell strain was also analysed to determine the relative DNA complements of the two strains. This analysis shows that the DNA complement of the transformed cells was almost twice that of the normal diploid cells, confirming that tetraploid cells dominate the population in the transformed strain[13].

Changes in the DNA distributions with time after heating at 43 °C are shown in Fig. 4. The points represent data from two or three experiments. The heating times were chosen to give about the same fractional survival in both cell populations (0.05). Accumulation of S-phase cells while the cells were at 43 °C together with a depletion of cells in G2-M may indicate a heat-caused block in the progress from S to G_2 in the transformed cells. Depletion of G1 also indicates a mitotic block during heating. After the return to 37 °C there was a steady increase in the G2-M population in both cell strains for 20–60 h, with a corresponding decrease in G1 and S populations. During the first 20 h this accumulation was probably the result of a continuing mitotic block for all cells. The populations were dominated by non-viable cells during the first few days after heating; the continuing accumulation in G2-M is thought to result from an accumulation of cells in late G2 or mitosis before cell death. Beyond 60 h viable cells have proliferated sufficiently to influence the DNA distributions and these gradually return to normal.

Assuming that the WI-38-VA13/2RA cells model the malignant cells of a human tumour whereas the WI-38 cells model the associated normal tissue, there seem to be inherent

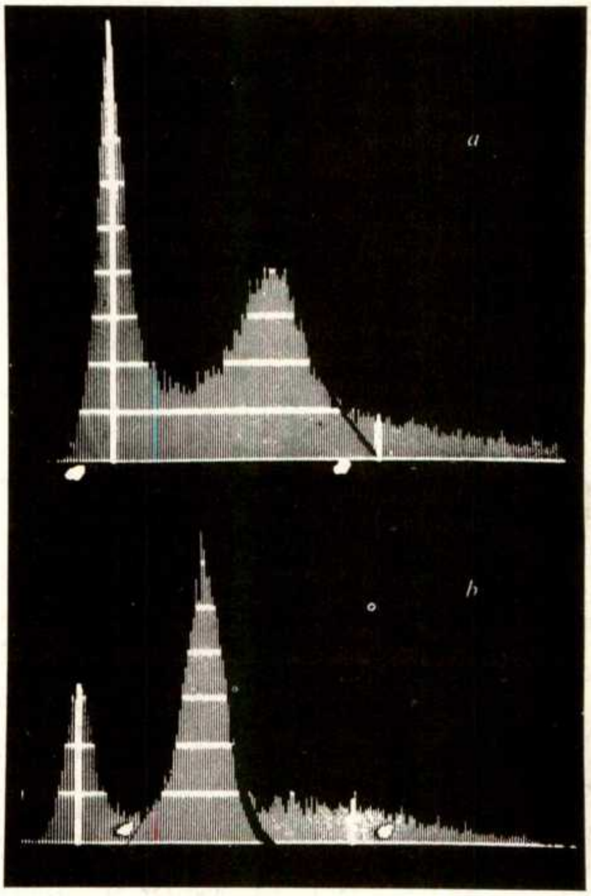

Fig. 3 DNA distributions of WI-38-VA13/2RA cells. *a*, Normal distribution of exponentially growing cells; *b*, distribution of cells 46 h after heating at 43 °C for 90 min.

differences in the hyperthermic response which may be exploited in cancer treatment. Not only are the transformed cells more readily destroyed by hyperthermia, but the differential cell kinetics that follow heating suggest that fractionated treatments involving either hyperthermia alone or in combination with radiotherapy or chemotherapy could further improve the therapeutic ratio.

We thank Dr L. Hayflick for WI-38 cells and Dr A. J. Girardi for WI-38-VA13/2RA cells. We also thank Drs H. Kaplan and A. Epstein for supplying the nude mice and for assisting in the tumorgenicity test, and Mr M. Hatfield for obtaining and analysing the DNA distributions. Organ specificity of blood-borne tumour metastasis determined by cell adhesion?

ONE of the most clinically troublesome aspects of cancer is metastasis, the spread of tumour cells from primary to distant, multiple secondary sites[1–3]. Metastasis initially occurs through tissue invasion, followed by transportation of tumour cells through the circulatory system, lymphatics or coelomic cavities[1,2]. In blood-borne metastasis free tumour cells or cell aggregates are carried into various organs and tissues where they stop in the first capillary bed encountered; however, most of these arrested tumour cells break loose, recirculate and stop in other organs[4,5]. In many tumour systems the location and extent of established secondary tumour colonies are non-random, suggesting that unique cell properties are important in tumour arrest and metastasis[3,6]. In support of this hypothesis Fidler[7] was able to select from a murine B16 melanoma line variants that showed enhanced metastatic behaviour by repeated cycling of tumour cells from lung colonies to tissue culture, administering the tumour cells intravenously on each cycle. We report here the organ adhesive specificity of four B16 variant cell lines selected for enhanced lung metastasis.

B16 variant melanoma lines with increasing ability to form lung metastases from subcutaneous or intravenous administration were obtained from Dr I. J. Fidler (University of Pennsylvania). These B16 lines are designated F1, F5, F10 and F13 based on the number of *in vivo* selections. The metastatic properties of these B16 variants are stable and not dependent on cell growth conditions[7]. Melanoma variants were grown *in vitro* in Dulbecco's modified Eagle's MEM[8] (DMEM) supplemented with 10% foetal calf serum, glutamine and non-essential amino acids. Cells were collected with EDTA as described previously[9]. The variant lines were also grown *in vivo* by intraperitoneal implantation in syngeneic C57BL/6J mice. After 2 weeks cells were collected from the peritoneal cavities and gently dispersed in DMEM through 200-mesh stainless steel filters. Contaminating phagocytic cells averaged less than 5% and viability assessed by dye exclusion averaged greater than 96%.

To assay organ cell adhesive properties single cell suspensions of lung, liver, kidney, brain and spleen were obtained from naive, syngeneic animals as follows. Organs were removed from 6–12 adult mice, pooled according to organ type and cut into 2–4-mm pieces in 10 ml of cold DMEM without serum and washed in DMEM. All steps were performed at 4° C. Dispersion of organs into single cells was accomplished by gently teasing the tissue pieces over the stainless steel filter with a Teflon policeman. Cell suspensions were rinsed by centrifugation (800*g*, 10 min) twice with 15 ml volumes of 0.05 M sodium phosphate-buffered saline (PBS) *p*H 7.4. Single, viable organ cells were isolated from cell debris, erythrocytes, platelets and cell aggregates by the two-step isopycnic-rate zonal gradient technique of Perper *et al.*[10]. Isopycnic centrifugation in Ficoll-Hypaque gradient yielded viable single cells with some membrane contamination. Subsequent centrifugation in discontinuous sucrose density gradients (5–20–30% w/v sucrose in PBS) separated erythrocytes, platelets and membrane debris (5% layer) and some minor cell-aggregates (30% layer) from single organ cells (20% layer). Final organ cell suspensions were rinsed free of sucrose by centrifugation in PBS and contained less than 5% erythrocytes by conventional

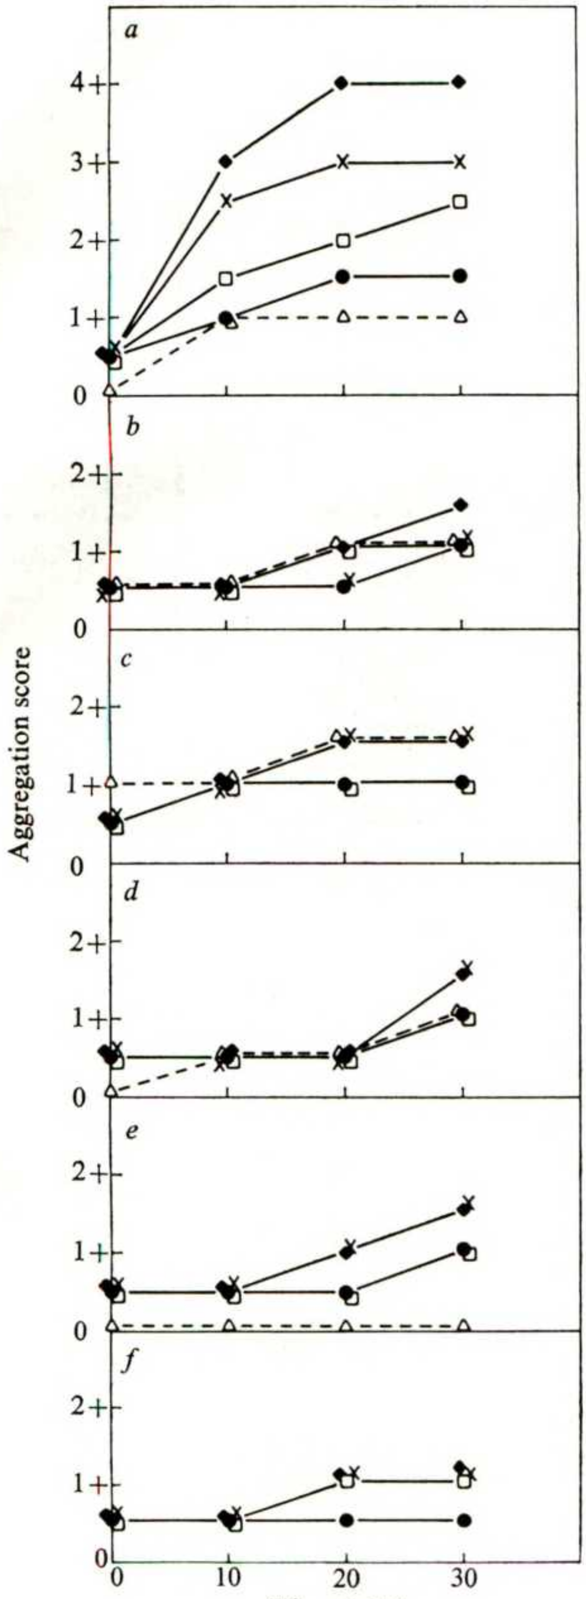

Fig. 1 B16 tumour cell aggregations with murine C57BL/6J organ cells. *a* Lung; *b* liver; *c* spleen; *d* kidney organ cell suspensions; *e* erythrocytes and *f* tumour cells alone. Extent of aggregation is scored from 0 (no aggregation) to 4+ (complete aggregation) (see text for details on the assay). These results were confirmed in three separate experiments using coded triplicate samples for each point. B16 melanoma cells were used at 1×10^6 ml^{-1}. ●, F1; □, F5; ×, F10; ◆, F13 and △, organ cells. Lung, liver, spleen and kidney were used at 3×10^6–5×10^6 ml^{-1} whereas the erythrocyte concentration was 1×10^7 ml^{-1}.

Wright's stain. Viability was greater than 97% as judged by dye exclusion, and contamination by phagocytic cells averaged less than 7%.

The aggregation assay was performed in 0.4 ml of medium containing 2% foetal calf serum using Linbro FP54 trays. Cells were dispensed into each well on the basis of their approximate surface area (see legend to Fig. 1), and the trays were rotated at 2 Hz on a rotary platform[9,11,12] for various times at 37 °C. Aggregation was scored as before[9] from 0 (no aggregation; 90–100% single cells), 1+ (scant aggregation; 60–90% single cells), 2+ (moderate aggregation; 30–60% single cells), 3+ (strong aggregation; 5–30% single cells) to 4+ (complete aggregation; 0–5% single cells). The reliability of this assay has been monitored and confirmed by electronic particle counting techniques[12] and adherence of ^{125}I-5-iodo-2′-deoxyuridine-labelled cells to cell monolayers J. L. W. and G. L. N., unpublished).

When melanoma variant cell lines are suspended with partially purified organ cells, heterotypic aggregation occurs[13]. This aggregation is specific and is related to the preferred organ site for implantation. The tumour lines selected for more lung metastases showed greater organ specific aggregation: lung>liver, kidney, spleen, erythrocytes (Fig. 1). With suspended lung cells the extent of aggregation paralleled the number of metastatic selections that the lines had undergone *in vivo:* F13>F10>F5>F1 (Fig. 1*a*). There was less aggregation with non-target organ cells, with little indication of selective aggregation by the more metastatic lines (Figs 1*b*–*e*). B16 tumour cells also homotypically (self) aggregate (J. L. W. and G. L. N., to be published). There was significantly less homotypic than heterotypic aggregation with lung cells (Fig. 1*f*), but the

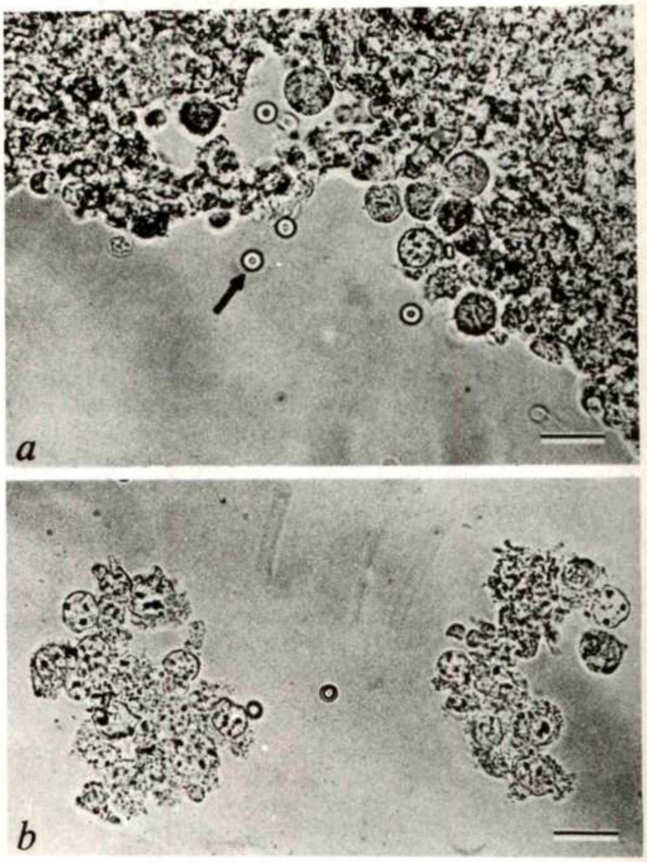

Fig. 2 Heterotypic cell aggregates formed with B16 variants and organ cells. *a*, B16-F13 variant aggregated with lung cell suspension for 20 min at 37 °C results in complete aggregation and the formation of one large mixed cell aggregate (4+ aggregation); *b*, B16-F5 variant aggregated with lung cells for 20 min at 37 °C (2+ aggregation). Arrow indicates unaggregated erythrocyte. ×420; bar represents 10μm.

difference was small or non-existent in homotypic and non-lung heterotypic aggregation experiments (Fig. 1*b–e* and our unpublished results). Microscopic examination of wells containing 4+ aggregates of lung and F13 cells revealed practically no free cells, indicating complete aggregation (Fig. 2*a*). Heterotypic aggregates formed with lung cells and B16 lines or with other organ cell suspensions were heterogeneous in cell composition (Fig. 2*b*). The existence of mixed aggregates of tumour and organ cells was confirmed by double labelling techniques (work unpublished). Soon after initiating the assay (10 min) there was little evidence of nonspecific cell aggregation (Fig. 1*e–f*).

The preferential adhesion to lung cells of the increasingly metastatic B16 variant lines seems to be paralleled by tumour cell behaviour *in vivo*. Injection of ^{125}I-labelled cells of the B16 variant into the tail vein of syngeneic mice results in 100% lung arrest of the B16-F11 and -F6 lines and approximately 80% lung arrest of the F1 line within 2 min. By 4 h 90, 80 and 55% and after 3 d 47, 35 and 2% of lines F11, F6 and F1, respectively remain in the lungs[14]. These results parallel closely the number of resulting lung tumour colonies visible within 3–4 weeks in the animals. Subcutaneous implantation of B16 metastatic variant cells in syngeneic hosts followed by removal of the primary subcutaneous tumours 1 to 2 weeks later results in spontaneous lung metastases within 6–8 weeks, the number formed being proportional to the number of *in vivo* selections F10>F5>F1 (ref. 14). These results indicate that initial cell–cell recognition during tumour cell arrest in specific organs may be one of the most important steps in the spread of blood-borne tumours.

Recent observations suggest that the success of tumour implantation and subsequent metastatic growth are determined by unique cell surface properties. Treatment of tumour cell surfaces with trypsin, neuraminidase[15–17], heparin[18,19] or dextran[20] before intravenous introduction modifies arrest and tumour distribution. Surface interaction of blood-borne tumour cells with lymphocytes[14] and platelets[21] can also affect the fate of circulating tumour emboli. Using B16 metastatic variants, Bosmann *et al.*[22] reported differences in surface proteases, glycosidases, glycosyltransferases and electrophoretic mobilities between low and high metastatic lines. These studies suggest the importance of cell surface properties in determining the *in vivo* fate of tumour cells.

Our results argue against an entirely nonspecific trapping mechanism for circulatory tumour cell arrest[1,2] and suggest that cellular recognition is important in determining the organ specificity of metastatic tumour spread. Since highly metastatic B16 tumour cells cause virtually complete aggregation of suspended lung cells, it is possible that recognition occurs through surface structures common to most, if not all, lung cells. Several types of cells are obtained by the dispersion techniques used here (for example, lung tissue yields endothelial, type I and II epithelial cells, fibroblasts and others) (Fig. 2), but contaminating blood cells such as erythrocytes, platelets, glass-adherent phagocytic cells and so on can be removed by density gradient separation, particle phagocytosis and other techniques. The role of blood cell interactions in the arrest of tumour emboli[14,21] was not examined here, but we are investigating the adhesion of tumour cells to platelets, lymphocytes and macrophages that affect implantation. The ultimate biochemical determination of the surface structures involved in the adhesion of tumour cells to organ cells is feasible using closely related B16 tumour lines with different recognition and metastatic properties.

These studies were supported by a contract from the Tumour Immunology Program of the US National Cancer Institute and grants from the US Public Health Service, Human Cell Biology Program of the US National Science Foundation and the Jane Coffin Childs Memorial Fund for Medical Research. Embryonic use of egg shell calcium in a gastropod

THE function of the calcified outer eggshell found in many gastropod eggs which are deposited on land has been the subject of considerable speculation. Various theories of its relationship to desiccation, mechanical support, protection against predators, physiological buffering and possible calcium source have been discussed[1-4]. This report presents the first quantitative analysis proving that a gastropod embryo uses the egg shell calcium in forming its embryonic shell, the protoconch.

The egg of the land pulmonate *Anguispira alternata* (Stylommatophora: Endodontidae) was examined during its development. This snail deposits eggs which have a heavily calcified, solid $CaCO_3$ shell made of calcite[5]. Each snail deposits 20–50 eggs, 2.5 mm in diameter, at 20 min intervals during a laying period. Hatching time is approximately 50–60 d at 20 °C; in land pulmonates there is usually a very large amount of variance in the rate of development and consequently in the time of hatching.

The egg shell and egg contents (albumen fluid) were analysed separately for calcium. After 20, 30, and 43 d incubation at 20 °C the eggs were opened and the embryos and egg shells analysed separately for total calcium content (Tables 1 and 2). In the freshly deposited egg, the albumen and single-celled

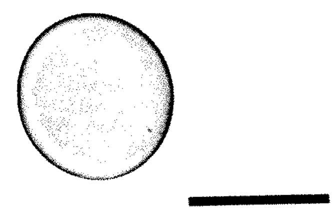

Fig. 1 Soft X-ray radiograph of a live, newly deposited *Anguispira alternata* egg. Bar represents 2 mm. For the generation of soft X rays, a GE Special Model F-5 machine with a beryllium tube and tungsten target was used. Operating conditions were 25 kV at 5 mA with Du Pont Ortho-Cronar Litho Film.

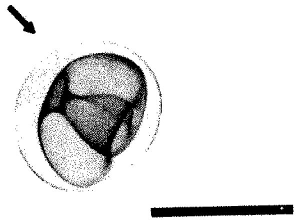

Fig. 2 Egg incubated at 20 °C for 43 d. The egg shell is now thinner and the embryonic shell, the protoconch, has formed at its expense. Arrow indicates where the snail will hatch. Live egg, exposure and printing as for Fig. 1. Bar represents 2 mm.

zygote together contain less than 1% of the total egg calcium; all the rest is in the egg shell. Between 20 and 30 d incubation, the embryo begins to absorb significant amounts of calcium from the egg shell. By 43 d of development, the embryos have absorbed up to 60% of the egg shell calcium. The range of results in Table 2 is a reflection of the staggering of developmental rates in land snails.

Table 1 Mean calcium distribution in the freshly deposited egg

Sample	Sample size	mg Ca per egg
Intact egg (shell + albumen)	5	0.608
Intact egg	5	0.490
Albumen	10	0.003
Albumen	5	0.002

The method of calcium analysis, neutron activation analysis, involves the conversion of a portion of ^{48}Ca, a stable isotope, to ^{49}Ca, which is unstable with a half life of 8.72 min, and measuring the characteristic γ radiation emitted. The source of neutrons was the Ford Reactor in the Michigan Memorial Phoenix Project, at the University of Michigan, the pneumatic tube system providing a flux of about 5×10^{12} n cm^{-2} s^{-1}. All the samples, in the milligramme range, were placed in polyethylene vials (cleaned with nitric acid) and freeze dried. They were then irradiated for 1 min, allowed to cool for 3 min, the entire vial was then placed near a 30 cm^3 germanium–lithium detector, FWHM 2.3 keV, connected to a 4,096 channel multichannel analyser calibrated to approximately 1 keV per channel with a CoCs source. Each sample was counted for 400 s. The calcium was measured using the 3,083 keV line of ^{49}Ca with reagent grade $CaCO_3$ powder as the standard. Calculations of the statistical counting errors and variability of controls and standards indicate a possible error of ± 10%. Whether these minute (2 mm) and very thin (30 µm) egg shells were crushed or not, made no difference in the results at this level of analysis.

Figures 1 and 2 show X-ray radiographs of a freshly deposited egg and an egg incubated for 43 d respectively. Both eggs were placed on the same piece of film, exposed and then printed together. Note that whereas the egg shell is made of calcite, the protoconch is made of another polymorph of $CaCO_3$, aragonite. The arrow in Fig. 2 indicates the area in which the embryo has most greatly weakened the egg shell, and at which it will break out. The mechanism of egg shell dissolution and reabsorption is not clear. When the embryo hatches, it consumes any egg shell remnants which are left.

There is evidence that this process of egg shell dissolution occurs in many other families of snails[6]. Calcified eggs have also been reported from land archaeogastropods[7] and from some of those mesogastropods which deposit their eggs on land[8]. It is suggested that land snails evolved the calcified egg shell early in their ancestry. For these terrestrial animals, calcium is often the limiting factor[9]. It would seem to be of great advantage to have the body shell already calcified by the time of hatching, for protection against small predators.

Embryonic absorption of egg shell calcium has been documented in some insects[10], some reptiles and birds[11]. A study of the calcium mobilisation in gastropod embryos with these other groups would be most rewarding from a comparative point of view.

Depressant action of TRH, LH-RH and somatostatin on activity of central neurones

THREE structurally identified hypothalamic-adenohypophyseal regulatory peptides—thyrotropin-releasing hormone (TRH)[1,2], luteinising hormone releasing hormone (LH–RH)[3,4] and growth hormone-release inhibiting hormone (somatostatin or SRIF)[5], have now been localised both in extrahypothalamic regions of the central nervous system (CNS)[6–9] and in certain extraneural regions, such as the pineal gland[10]. There is increasing evidence that these peptides may affect behaviour by direct action on the brain. Systemic administration of TRH to rats induces behavioural effects independent of the pituitary–thyroid axis[11]; LH–RH can induce mating behaviour in hypophysectomised female rats[12], and somatostatin potentiates the behavioural effects of d,l-dopa[13]. These findings together with evidence of high affinity binding sites for TRH in extrahypothalamic tissues[14], identification of LH–RH in synaptosome fractions of brain[15] and localisation of LH–RH[16,17] and somatostatin[18,19] in nerve terminals suggest a role for these peptides in neuronal function. Applying TRH, LH–RH and somatostatin directly to central neurones microiontophoretically, we have found that these peptides have a potent depressant action on the activity of neurones at several levels (cerebral and cerebellar cortex, brain stem and hypothalamus) of the neural axis.

Experiments were performed on male Sprague Dawley rats anaesthetised with urethane (1.25 mg kg^{-1} intraperitoneally in 25% w/v solution) or pentobarbital (50 mg kg^{-1} intraperitoneally with supplemental intravenous doses). In experiments in which extracellular records were obtained from neurones in the cerebral or cerebellar cortices or the cuneate

Table 1 Summary of depressant responses observed from central neurones during microiontophoresis of hypothalamic releasing (or release inhibiting) peptides

	Site	No. tested	No. responsive	Effective current range* (nA)
TRH	Cuneate nucleus	43	12 (28%)	6–20
	Cerebellar cortex	66	28 (42%)	5–30
	Cerebral cortex	36	17 (47%)	15–25
	Hypothalamus (HVM)	50	30 (60%)	10–18
LH–RH	Cerebellar cortex	17	13 (76%)	5–25
	Hypothalamus (HVM)	16	13 (81%)	10–30
Somatostatin	Cerebellar cortex	9 (L)	5 (55%)	7.5–20
		9(C)	5 (55%)	10–25
	Cerebral cortex	13 (L)	11 (84%)	10–30
		15 (C)	12 (80%)	10–30
	Hypothalamus (HVM)	14 (C)	11 (78%)	15–35

All other neurones were unresponsive. Somatostatin was tested in both the linear (L) and cyclised (C) form. HVM, hypothalamic ventromedial nucleus.

* Range of iontophoretic currents which yielded clear depressant effects within 10 s of application. The range of values for either the peptides or the areas does not differ significantly.

nucleus, exposed surfaces were irrigated continuously with mammalian Ringer solution. The hypothalamus was exposed by a retropharyngeal approach, and neurones in the ventromedial nucleus were identified by a characteristic orthodromic response to stimulation of the amygdala or stria terminalis[20]. Single unit activity was recorded with micropipettes filled with 3.0 M NaCl and the frequency of spike discharges, selected with a voltage gate, was monitored on a polygraph. For microiontophoresis, five or seven-barrelled micropipettes were fixed rigidly to the side of the recording micropipette, and the tips were separated by 10–15 μm. Solutions of TRH, LH–RH or somatostatin dissolved in distilled water (5 mM) were placed in microiontophoretic channels and ejected as the cation. Adjacent channels always contained sodium L-glutamate (1.0 M., *p*H 7.0) to excite otherwise silent neurones, and sodium chloride (10 mM) as a current control.

In each area of the CNS studied, only a certain population of neurones responded to microiontophoretic application of individual peptides (Table 1). In responsive neurones, all three peptides depressed discharge frequency (Fig. 1) often in association with an increase in spike size, suggesting membrane hyperpolarisation. For some cells, iontophoretic currents as low as 5–10 nA effected a 50% reduction in spike discharge frequency of both spontaneous and glutamate-evoked activity. The characteristics of the responses in sensitive cells were similar with each peptide: brevity in onset after application of current, rapid recovery after cessation of the ejection current, graded decrease in excitability with increased current, reproducibility with successive applications and lack of similar responses during application of positive control currents (sodium ions). The spike discharge frequency of insensitive neurones showed no consistent change when peptides were applied even with currents as high as 100–160 nA.

Twelve of fourteen peptide-sensitive neurones (six in the cerebellar cortex, four in the cerebral cortex, four in the hypothalamus) were sensitive to both TRH and LH–RH (Fig. 2*b*) although the two remaining neurones were responsive to LH–RH only (Fig. 2*a*). TRH sensitive neurones, more frequent in hypothalamus than elsewhere in the brain, were also found in the cerebellar cortex although this area has a low content of TRH[6] and lacks high affinity TRH binding sites[14]. A wide range of TRH responsiveness for neurones in any one area of the CNS has been reported[21]. As indicated in Table 1, a substantial number of neurones was responsive to LH–RH and somatostatin even in areas where these peptides have either not been detected or are low in concentration. Somatostatin was effective when applied in either the linear or the cyclised (dihydrosomatostatin) form.

Our observation that hypothalamic peptides have potent depressant actions on the excitability of a certain population of neurones in several areas of the CNS extend studies which indicate a depressant action of TRH[21,22] and LH–RH[22,23] when applied to hypothalamic neurones; it seems, however, that this response pattern is not solely restricted to hypothalamic neurones involved in pituitary regulation. This more generalised distribution of peptide-sensitive neurones supports the hypothesis that these peptides are involved in

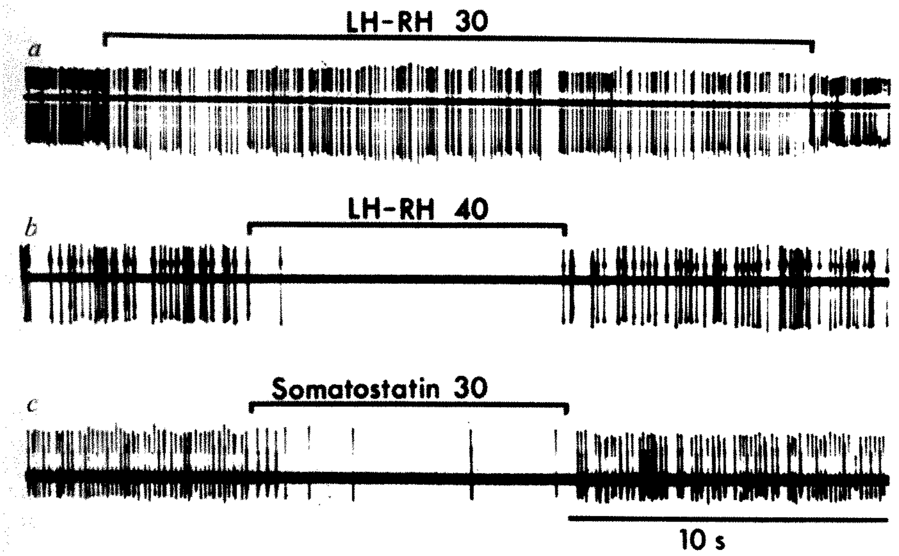

Fig. 1 Representative continuous oscillograph traces to indicate effects of microiontophoresis of LH–RH and somatostatin. Note the increase in spike amplitude (*a*) and decrease in spike discharge frequency which accompanies applications of LH–RH to two hypothalamic neurones located in the ventromedial nucleus (*a*, *b*) and cyclised somatostatin to a neurone in the parietal cortex (*c*). Numbers above each bar indicate the microiontophoretic current (in nA) used to apply each hormone. Time calibration, 10 s.

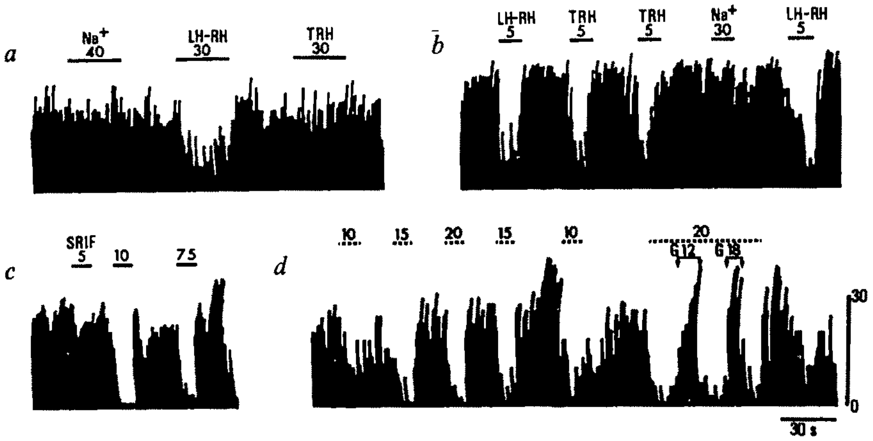

Fig. 2 Polygraph traces of changes in spike discharge frequency of three spontaneously active cerebellar cortical neurones (*a–c*) in response to microiontophoresis of TRH, LH-RH and somatostatin. Cell *a* was responsive to LH-RH but not to either TRH or positive current. The firing frequency of cell *b* was depressed by both TRH and LH–RH. The tracing in (*c*) indicates a neurone the activity of which was depressed by cyclised somatostatin. *d*, Linear somatostatin depressed the spontaneous activity of a parietal cortical neurone. This depression remained stable during longer periods of application and could be overcome by brief applications of L-glutamate (arrows). Vertical calibration bar indicates c.p.s.

the modulation of central neuronal activity. Microiontophoretic studies with substance P, another peptide found in the hypothalamus, indicates a predominantly excitatory action when applied to neurones elsewhere in the brain[24]. Microiontophoretic application of angiotension II was also reported to excite central neurones[25].

An understanding of the role of hypothalamic peptides in neuronal function requires data on their ultrastructural localisation and demonstration of their release from synaptic nerve terminals after stimulation. In support of the latter possibility is recent electrophysiological evidence that axons of certain tuberoinfundibular neurones have two (or more) collaterals, one of which terminates on the portal vessels of the median eminence, while the other either terminates locally within the hypothalamus (anterior hypothalamic–preoptic area) or exits from the hypothalamus to other regions of brain[26]. Thus it is possible that hypothalamic releasing or release-inhibiting peptides are liberated simultaneously both at central synapses as well as at the median eminence terminals of tuberoinfundibular neurones, thereby acting both as neural transmitters and as neurohormones, an earlier suggestion for another hypothalamic peptide, vasopressin[27].

We thank Mr Brian MacKenzie for technical assistance, Mrs M. Walker for typographical aid, Mr W. F. White (Abbott Laboratories, Chicago) for TRH and LH–RH, Dr M. Goetz (Ayerst Laboratories, Montreal) for somatostatin, and the Medical Research Council of Canada for financial support.

Dopamine depolarising response in a vertebrate neuronal somatic cell hybrid

THERE are various lines of evidence that the catecholamine dopamine (DA) is a neurotransmitter in both invertebrate and vertebrate nervous systems[1–4]. In support of this concept, we report depolarising responses to DA caused by a conductance increase and detected by intracellular recording from a vertebrate somatic cell hybrid of neuronal origin.

Somatic cell hybrids are derived from the fusion of two cell types, producing a dividing cell population that expresses properties contributed by each of the parent cells[5–6]. Hybridisation of cells of neuronal origin has resulted in clonal lines that express several neuronal characteristics[7–9]. We used 108CC-15 (also designated NG108-15), which is a somatic cell hybrid of the mouse neuroblastoma N18TG2 and the rat glioma C6-BU-1. Although one parent was of glial origin, the hybrid has numerous properties of nerve cells such as neurone-like morphology, dopamine-β-hydroxylase activity, choline acetyltransferase activity, dense-core and clear vesicles and sensitivity to acetylcholine[10–12]. Thus for descriptive purposes the hybrid cell is neuronal and can provide data relevant to the role of DA in an organised nervous system. The advantage of 108CC-15 for investigating receptor mechanisms are: (1) it provides a large homogeneous cell population free of the anatomical complexity of organised tissues; (2) there is no extrinsic synaptic input, facilitating study of single units with DA receptors; (3) the cells are in an isolated, controlled environment that can be easily manipulated, and (4) the cells are large (40–70 μm) and intracellular recordings can be made with relative ease.

The average membrane potential of 111 cells was −42.5 mV with an average input resistance of 39 MΩ. Detailed analysis of the electrical properties of this cell line has been presented elsewhere[13].

Figure 1*A* shows the membrane response to graded amounts of DA. Sixty-four per cent of the 111 cells penetrated gave a depolarising response to DA with an associated decrease in resistance (increase in conductance). The rise time of the response varied with the proximity of the DA iontophoretic electrode to the membrane. 3-Methoxytyramine-HCl (Sigma) was also applied iontophoretically so as to rule out a response elicited by nonspecific *p*H effects or a physical stimulus from the current. 3-Methoxytyramine caused no potential or conductance changes in five cells tested but an equal charge of DA gave a response as described above, adding credence to the specificity of the receptor for DA. Repeated applications of DA at short intervals resulted in membrane desensitisation and temporary reduction or loss of the response (Fig. 1*B*). Similar findings have been reported for the excitatory DA response in Aplysia neurones[14]. Iontophoretically applied noradrenaline (NA) depolarised the membrane but the response amplitude was less than that produced by an equal iontophoretic charge of DA. In addition, the membrane became desensitised to DA when NA was applied repeatedly. These results indicated that DA and NA had common receptors, but that DA was more efficacious. Other investigators using 108CC-15 have found that NA and DA both depolarise the membrane (J. Traber, G. Reiser, K. Fischer and B. Hamprecht, personal communication).

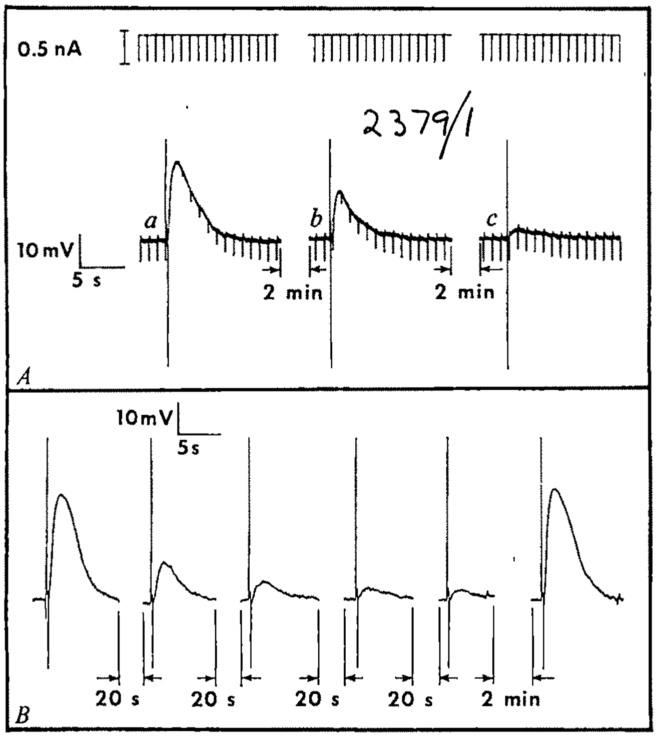

Fig. 1 *A*, DA depolarising response with a conductance increase. Top trace: current pulses passed across the membrane. Lower trace: dose-response characteristic of iontophoretically applied DA obtained by varying the amount of charge delivered. *a*, 600 nC; *b*, 300 nC; *c*, 100 nC. Current pulses indicate the change in resistance. Cells were grown in Falcon dishes with modified F12 medium[18] supplemented with 5% foetal calf serum, hypoxanthine (30 μM increased to 100 μM), aminopterin (0.4 μM) and additional thymidine (3.0 μM increased to 16 μM) at 37 °C and 5% carbon dioxide: 95% air in a water saturated atmosphere. For experiments, 10^4 cells were seeded into 35mm Falcon dishes and grown for at least 7d in medium free of aminopterin but supplemented with 1 mM dibutyryl cyclic adenosine monophosphate (Sigma). The drug induces morphological and biochemical differentiation of neuroblastoma cells in culture[11,19-22]. Standard electrophysiological techniques using a bridge circuit were used to record membrane potential while passing current intracellularly. Glass microelectrodes filled with potassium acetate and potassium chloride and resistances greater than 30 MΩ were used for intracellular recording. For iontophoresis, 1 M dopamine-HCl (Sigma) was dissolved in distilled water and used to fill glass micropipettes (electrode resistance 10–20 MΩ). During recording, culture dishes were maintained at 37 °C and gassed with a stream of water-saturated 10% CO_2: 90% air. *B*, Desensitisation of the receptor by DA. Iontophoretically applied DA was delivered at short time intervals to demonstrate reduction in response amplitude and full amplitude recovery after a longer time interval. Iontophoretic charge was 500 nC.

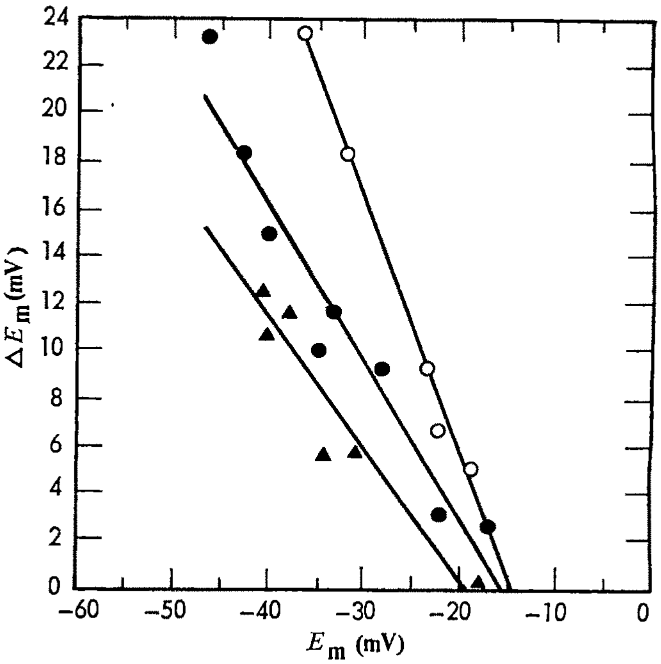

Fig. 2 Reversal potential of the DA response for three cells. Depolarising current was passed across the cell membrane to alter the resting membrane potential. Equal amounts of DA were iontophoretically applied at selected membrane potentials and the response amplitude was determined. Lines were established by linear regression analysis of the data for each cell. The intercept at the abscissa represents the reversal potential.

Figure 2 is a plot of DA response amplitude compared with membrane potential for three individual cells. The intercept at the abscissa was −15.9 mV (±1.2; $n=4$) and represents the DA reversal potential. This value is similar to that found in vertebrate neuromuscular junctions where the acetylcholine response is mediated by an increase in sodium and potassium conductances[15].

Phentolamine, propranolol, chlorpromazine and bulbocapnine blocked the DA response when present in concentrations greater than 50 μM, which agreed with their known central actions. Phentolamine and propranolol are adrenergic blockers. Chlorpromazine is a phenothiazine which interferes with DA receptors[16] and bulbocapnine is a DA antagonist similar in structure to the agonist apomorphine[17].

These studies show that vertebrate cells of neuronal origin can exhibit depolarising responses to DA associated with a conductance increase. Cell preparations of this sort may be of further use in studies of receptor mechanisms in an isolated, controlled environment.

We thank Dr Berndt Hamprecht on whose cell line this study was completed and Drs William Shain and David Carpenter for helpful discussion.

Nerve terminal ATPase as possible trigger for neurotransmitter release

WHEN a wave of depolarisation spreads down an axon and invades the nerve terminals a number of events rapidly occur and it is difficult to establish the one ultimately responsible for the release of neurotransmitter. There is strong evidence to support the contention that calcium ion influx is involved both in the release of acetylcholine[1] and of noradrenaline[2], but ion-exchange processes at the level of the vesicle, not necessarily directly involving calcium have been proposed[3], and the concept of regulation of release through changes in the activity of an adenosine triphosphatase (ATPase) has also been invoked[4,5]. This paper is concerned with the last possibility. Following the inward movement of sodium ions, the inward movement of calcium ions to the enzyme on the inner edge of the nerve terminal membrane would be expected to inhibit the activity of sodium, potassium-activated, magnesium-dependent ATPase (Na,K-ATPase)[6]. Sodium depletion, or the addition of ouabain to preparations *in vitro* would also be expected to inhibit Na,K-ATPase activity. These three conditions of enzyme inhibition have all been shown to result in increased acetylcholine release[4,5].

We have already suggested elsewhere[7–9] that nerve ending particles (synaptosomes) prepared from rat cerebral cortex contain an ouabain-insensitive component of that ATPase activity which is apparently activated by sodium and potassium ions in the presence of magnesium ions, and which is generally assumed to represent Na,K-ATPase. This apparent Na,K-ATPase activity was calculated by subtracting the magnesium-ATPase (Mg-ATPase) activity, determined by measuring the release of inorganic phosphate from Tris-ATP (4 mM) in 50 mM imidazole- HCl buffer *p*H 7.4 containing 5 mM $MgCl_2$, from the total ATPase activity determined in a similar mixture which also contained NaCl (150 mM) and KCl (10 mM). The reaction time was 10 min in each case and sodium dodecylsulphate (0.8%) was used to stop the reaction[9]. The ouabain-insensitive component, the existence of which has recently been supported by others[10,11], is the result of sodium-activated, magnesium-dependent ATPase (Na-ATPase) activity[9], determined by measuring the hydrolysis of ATP in the $MgCl_2$-containing buffer to which NaCl (150 mM) has been added. Note that in synaptosomes, at least, the magnitude of this activity varies with the species of animal, the values for the rat, mouse and guinea pig being 33, 13 and 43% of the apparent Na,K-ATPase activities, respectively.

The implications of the existence of a Na-ATPase together with a true Na,K-ATPase (the ouabain-inhibited enzyme requiring sodium and potassium ions together) in the nerve terminals are considerable if the hypothesis is proposed that inhibition and stimulation of the activities of ATPases are involved in the regulation of neurotransmitter release. We report here data concerning the effects of noradrenaline, phentolamine and acetylcholine on the activities of these enzymes in synaptosomes prepared from rat cerebral cortex as described previously[9].

Noradrenaline (5×10^{-5}–1×10^{-3}M) stimulated both the Na- and the Na,K-ATPase activities of the synaptosomes (Table 1). Other workers[10,11] have also detected stimulation of Na,K-ATPase by noradrenaline and our results indicate that the Na-ATPase is affected to approximately the same extent as the Na,K-ATPase. Moreover, stimulation of the two enzymes by noradrenaline was decreased by approximately the same extent by the α-adrenoceptor antagonist phentolamine (10^{-5} M, lower concentrations being less effective). In direct contrast to the effect of noradrenaline, acetylcholine (10^{-4}–10^{-3}M) inhibited the Na,K-ATPase but the activity of the Na-ATPase was not altered in the conditions used.

Table 1 Effects of noradrenaline, phentolamine and acetylcholine on ATPase activities of synaptosomes prepared from rat cerebral cortex

Drug	Concentration (M)	Relative ATPase activities* NaK	Na
None		100	100
Noradrenaline	1×10^{-6}	$107.0\pm3.9(5)$	$96.1\pm6.4(5)$
	5×10^{-5}	$132.5\pm2.5(2)$	$135.0\pm6.9(2)$
	1×10^{-4}	$141.3\pm3.0(3)$	$136.3\pm16.3(3)$
	1×10^{-3}	$145.2\pm5.9(5)$	$139.3\pm10.0(5)$
Phentolamine	1×10^{-5}	$100.0\pm2.0(2)$	$97.4\pm1.7(2)$
Phentolamine Noradrenaline	1×10^{-5} 5×10^{-5}	$99.8\pm2.6(2)$	$102.4\pm2.4(2)$
Acetylcholine	1×10^{-5}	86.8 (1)	97.5 (1)
	1×10^{-4}	$58.5\pm2.6(2)$	$100.9\pm3.4(2)$
	1×10^{-3}	$60.1\pm0.7(3)$	$97.1\pm6.7(3)$

Numbers of observations in parentheses.

*Results expressed as percentages of control values typically $6.4\pm0.5(21)$ and $3.3\pm0.3(22)$ μmol inorganic phosphate per mg protein per h for the Na,K- and the Na-ATPases, respectively. Percentage values under the different conditions have been calculated by comparison with paired controls of the same series.

These results should be considered in the light of evidence suggesting that noradrenaline released from the nerve terminal can cause feedback inhibition of further release[12,13]. Nerve terminal ATPases may be involved in this mechanism. Thus, although inhibition, of Na,K-ATPase by calcium ions, for instance, may increase neurotransmitter release, stimulation of this enzyme, or of a closely related one, may depress it. The effect of phentolamine in preventing the stimulation of both the Na,K-ATPase and the Na-ATPase by noradrenaline is then compatible with the proposition that feedback inhibition is mediated through α-adrenoceptors[12,14].

Although stimulation of both Na- and Na,K-ATPase could be involved in noradrenaline-mediated depression of noradrenaline release, any modulation of this release at synapses by acetylcholine is likely to be through effects on Na,K-ATPase alone (Table 1), inhibition of the enzyme presumably increasing noradrenaline release. Whether or not inhibition of Na,K-ATPase by acetylcholine should be viewed in the light of the suggestion of Langer[15] that presynaptic nicotinic and muscarinic receptor activation can influence noradrenaline release, or in the light of the cholinergic link hypothesis of Burn and Rand[16] is a matter for conjecture; but at least the change in the activity of the enzyme is in the right direction to permit reconciliation with these ideas as well as with the better documented evidence linking increased neurotransmitter release with such factors as calcium ion entry.

Modulation of neurotransmitter release is also believed to be an important function of prostaglandins. Hedqvist[17] showed that the noradrenaline release associated with electrical stimulation of nerves supplying the perfused cat spleen was inhibited by prostaglandins of the E series and he later found that the inhibitory effect of prostaglandin E_2 (PGE_2) was antagonised by calcium ions[18]. We have observed[9] that PGE_1 stimulates synaptosomal Na,K-ATPase activity. Here again it could be assumed that stimulation of the Na,K-ATPase inhibits neurotransmitter release, and that the inhibitory effect of calcium ions on the activity of the enzyme antagonises this process.

Evidence for a more direct association between the activities of ATPases in the nerve terminals and the regulation of neurotransmitter release should be obtained before the hypothesis is strongly supported. The mechanism of regulation by the enzymes requires consideration although one could propose that a change in the local environment of a membrane-bound enzyme results in both a change in its activity and its conformation such that an increase in exocytosis occurs. It could be argued, however, that the rates of activity of the enzymes are not sufficiently high to regulate neurotransmitter release to a fine degree by such a mechanism. Again, the observations mentioned here in connection with the hypothesis are drawn from work involving both peripheral nerves and the central nervous system, and the information concerning the effects of drugs on the activities of the ATPases has come from work with cerebral cortex synaptosomes which contain at the least both cholinergic and adrenergic types. We feel, nevertheless, that the hypothesis merits further attention.

We thank Mrs Lorna Smith for assistance.

Oxygen control of cytochrome *c* oxidase synthesis in isolated mitochondria from *Saccharomyces cerevisiae*

DURING anaerobic growth *Saccharomyces cerevisiae* cells produce respiratory-deficient mitochondria-like structures—promitochondria—which contain a normal complement of mitochondrial DNA (mtDNA) and many mitochondrial enzymes but which lack cytochrome components of the inner mitochondrial membrane[1–4]. On exposure to oxygen these respiratory-deficient structures develop a full complement of cytochromes and differentiate into respiring mitochondria[5]. Although the precise mechanism by which oxygen mediates mitochondrial biogenesis is still incompletely understood recent studies with whole yeast cells have shown that one effect of oxygen is at the level of either synthesis or assembly of some mitochondrial translation products[6–8]. Unfortunately, these *in vivo* studies could not localise the primary effect of oxygen to the mitochondrion nor could they demonstrate that oxygen acts directly on mitochondrial protein synthesis rather than indirectly by inhibiting other biochemical reactions, for example in the biosynthesis of haem[9], required for the development of functional cytochromes. As a first step towards localising the effect of oxygen and ascertaining if it is indeed at the level of the mitochondrial protein synthesis we have studied the effect of O_2 on the *in vitro* synthesis of three mitochondrial translation products, subunits I, II and III of cytochrome *c* oxidase, by isolated mitochondria. We have found that mitochondria incubated in the presence of oxygen synthesise subunits I, II and III and assemble them with the four cytoplasmically-made subunits[8] into a holoenzyme[10], although mitochondria incubated in the absence of oxygen do not synthesise subunits I and II. These results demonstrate that oxygen acts directly on the mitochondrion and strongly suggest that at least one step in mitochondrial transcription-translation requires oxygen.

Table 1 Effect of anaerobiosis on the incorporation of ^{14}C-leucine into isolated mitochondria

Additions or omissions	Incorporation (c.p.m. per mg protein) Aerobic	Anaerobic
None	3,500	2,680
+ Chloramphenicol	314	258
+ Cycloheximide	3,550	—
− ATP, PEP, pK	—	1,000

Protein synthesis in isolated mitochondria was measured as described previously[10]. Anaerobic incubations were carried out in long test tubes with the reaction mixture covered with liquid paraffin. Five minutes after the oxygen was consumed by the respiring mitochondria (usually in 1–1.5 min as checked with a Clark oxygen electrode in a parallel incubation) the reaction was started by the addition of 0.2 µCi ^{14}C-leucine (60 mCi mmol^{-1}) per ml by means of a syringe fitted with a long needle.

Table 1 summarises the effect of anaerobiosis on the incorporation of radioactive leucine into acid-insoluble material by isolated mitochondria. Both aerobic and anaerobic incorporation show the expected response to chloramphenicol and cycloheximide, indicating that essentially all of the protein synthesis is taking place on mitochondrial ribosomes. Incorporation of radioactive leucine into protein in anaerobic conditions is dependent on the continuous supply of ATP by the ATP-regenerating system, phosphoenolpyruvate–pyruvate kinase, and is 50–70% (4 experiments) of that incorporated in aerobic conditions.

Table 2 Effects of anaerobiosis on the labelling of cytochrome *c* oxidase

Labelling condition	Experiment	Specific activity of labelled mitochondria (c.p.m. per mg protein)	Total mitochondrial label immuno-precipitated (%)
Aerobic	1	4.85×10^4	8.7
	2	3.33×10^5	10.4
Anaerobic	1	2.85×10^4	4.2
	2	1.59×10^5	6.0

Isolated mitochondria were pulse-labelled with 0.1 mCi ml^{-1} of L-4,5-^{3}H-leucine (3Ci mmol^{-1}) for 20 min either aerobically or anaerobically as described in Table 1. The labelled mitochondria were solubilised with cholate-KCl and subjected to immunotitration using an antiserum to holo-cytochrome *c* oxidase as described previously[10]. Values for the percentage of total mitochondrial label immunoprecipitated represent plateau values taken from immunotitration curves and have been corrected for nonspecific precipitation obtained with control serum.

The effect of oxygen on the *in vitro* synthesis of subunits I, II and III of cytochrome *c* oxidase was assessed by determining the amount of radioactivity precipitated from mitochondrial extracts by an antiserum to cytochrome *c* oxidase and analysing the immuno-precipitates by sodium dodecyl sulphate (SDS) gel electrophoresis. The immunotitration results shown in Table 2 indicate that labelling of cytochrome *c* oxidase in anaerobic conditions is reduced by about 50% relative to the aerobic control. Electrophoretic analysis (Fig. 1*a* and *b*) of the immunoprecipitates from aerobically and anaerobically-labelled mitochondria reveals that subunit III of cytochrome *c* oxidase is labelled both in the presence and absence of oxygen, but that subunits I and II are labelled only in the presence of oxygen. Since subunits I and II account for 40–50% of the radioactivity in immunoprecipitates from aerobically-labelled mitochondria it seems that the decreased level of anaerobic incorporation is caused solely by the lack of synthesis of these two subunits. This finding that subunits I and II are synthesised *in vitro* only in the presence of oxygen fully parallels the *in vivo* studies of Mason and Schatz[8] and, in addition, demonstrates that oxygen can act directly on the mitochondrion.

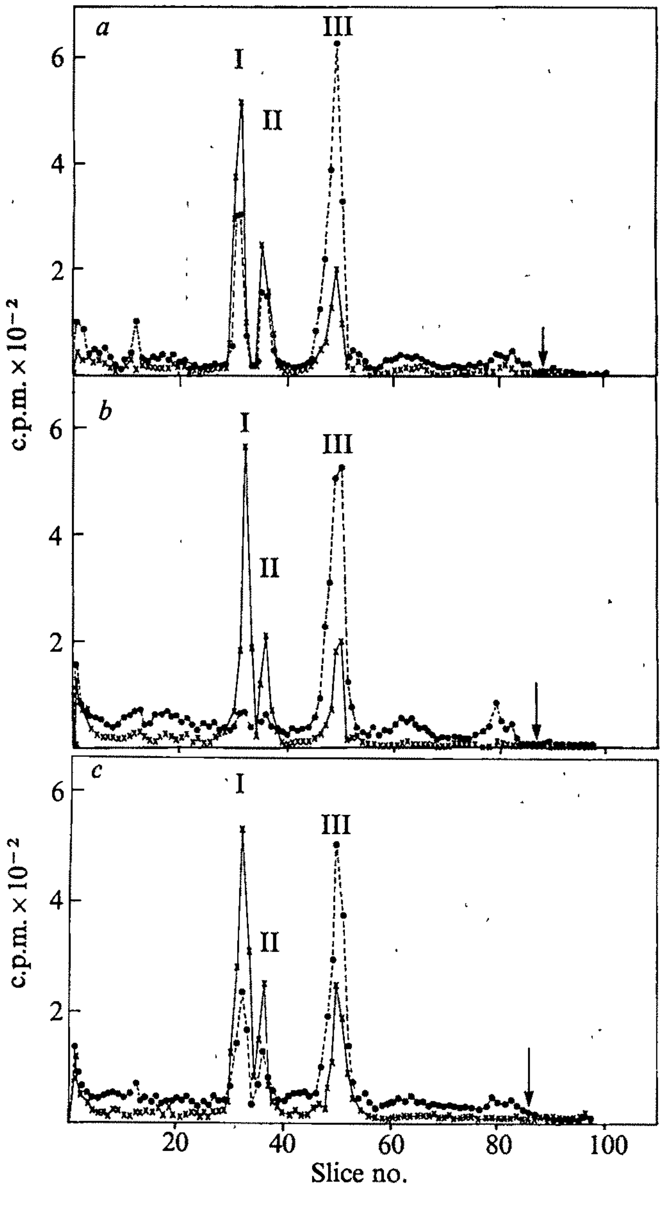

Fig. 1 SDS polyacrylamide gel analysis of cytochrome *c* oxidase immunoprecipitates from extracts of mitochondria labelled: *a*, aerobically; *b*, anaerobically; and *c*, aerobically after a 20 min anaerobic preincubation. Isolated mitochondria which were labelled *in vitro* with ^{3}H-leucine either aerobically or anaerobically were solubilised in cholate-KCl, mixed with mitochondrial extracts from cells labelled *in vivo* with ^{14}C-leucine in the presence of cycloheximide and subjected to immunoprecipitation[10] using an antiserum to holocytochrome *c* oxidase. The immunoprecipitates were solubilised in SDS and electrophoresed on 12% acrylamide–0.375% *bis*-acrylamide gels as described previously[13]. The arrow marks the position of the dye front. ×, ^{14}C-leucine counts immunoprecipitated from *in vivo* labelled mitochondria (cells + cycloheximide); ●, ^{3}H-leucine counts immunoprecipitated from *in vitro* labelled mitochondria.

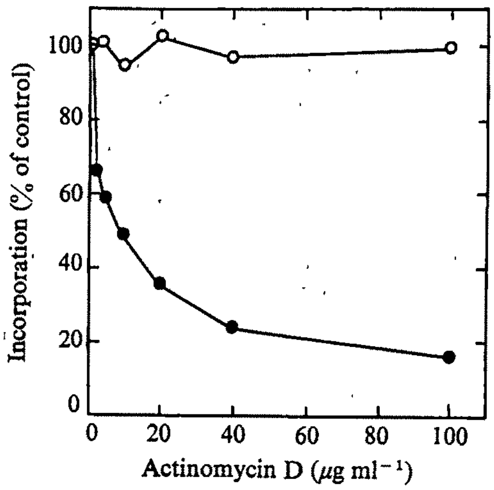

Fig. 2 Effect of actinomycin D on RNA and protein synthesis in isolated mitochondria. Mitochondria (2 mg) were incubated as described previously[10] and pulse-labelled for 20 min with 50 μM ^{3}H-UTP (10^6 c.p.m. nmol^{-1}) and 5 μM ^{1}-C-leucine (0.04×10^6 c.m.p. nmol^{-1}). Acid-insoluble counts were measured. The 100% value corresponded to 5 pmol ^{1}-C-leucine (○) and 0.5 pmol ^{3}H-UTP (●) incorporated per mg protein per min.

To exclude the general deleterious effect of the absence of oxygen on mitochondrial protein synthesis, we have tested the reversibility of the oxygen effect. To reproduce *in vitro* the "aerobic adaptation" phenomenon already well documented from *in vivo* studies we incubated isolated mitochondria anaerobically for 20 min and then aerated them in the presence of ^{3}H-leucine. A comparison of Fig. 1(*c*) with Fig. 1(*a*) reveals that subunits I and II are labelled to near normal levels after the anaerobic preincubation. Thus, it seems that the response of isolated mitochondria to the absence of oxygen is exactly like that of whole cells.

At the moment there seem to be three possibilities to explain the finding that subunit III of cytochrome *c* oxidase is unresponsive to oxygen although subunits I and II are positively controlled by it. First, oxygen may act at the level of mitochondrial transcription either by stimulating an RNA polymerase[11] or by inactivating a repressor[12]. This explanation assumes that the genetic information for subunits I and II of cytochrome *c* oxidase is present on mtDNA, an assumption for which there is no direct evidence. Second, oxygen may act at the level of mitochondrial translation, and third, oxygen may be required for the integration of polypeptide subunits (for example subunits I and II of cytochrome *c* oxidase) into enzyme complexes. For this explanation to be correct we would have to assume that subunits which are not integrated are rapidly degraded as they cannot be detected by immunoprecipitation. Since we have not observed a substantial increase in low molecular weight polypeptides in immunoprecipitates from anaerobically-labelled mitochondria we consider this explanation unlikely. While we cannot rule out the first possibility, some evidence against it is obtained from Fig. 2. Actinomycin D in a rather high concentration seems to be an effective inhibitor of mitochondrial transcription (inhibiting UTP incorporation up to 80%), whereas at the same concentration no effect is seen on the incorporation of leucine. This result indicates that mitochondrial translation is not dependent on at least the bulk of mitochondrial transcription. It seems unlikely, therefore, that inhibition of mitochondrial transcription would lead to the observed inhibition of incorporation of label into subunits I and II of cytochrome *c* oxidase. Thus, at the moment, it seems most likely that oxygen is regulating the synthesis of subunits I and II of cytochrome *c* oxidase directly at the level of mitochondrial translation.

We thank Mrs N. van Harten-Loosbroek and Mrs J. Kavanagh for technical assistance, and Dr P. Borst for discussions. Molecular basis for the α_1-protease inhibitor deficiency

THE α_1-protease inhibitor (formerly α_1-antitrypsin) is inherited by a series of autosomal codominant alleles that determine its concentration and electrophoretic mobility. Serum from individuals with severe α_1-protease inhibitor deficiency usually contains an electrophoretically slow-moving α_1-protease inhibitor (type ZZ) in an amount 10–40% of that found in the normal population (type MM). This deficient state is associated with either an early-onset form of familial emphysema or familial infantile cirrhosis[1].

So far, however, the molecular basis for this deficiency has not been established although Bell and Carrell[2] and Cox[3] suggested that the Z protein lacked some of the sialic acid residues found in the normal protein. They reasoned that a glycoprotein with fewer terminal sialic acid residues could be expected to accumulate intracellularly by binding to the plasma membrane of liver cells, thus effectively decreasing the concentration of the circulating protease-inhibitor. This hypothesis is consistent with a report[4] of patients with severe α_1-protease inhibitor deficiency (type ZZ) whose serum was markedly deficient in sialic acid transferase activity. We have now found that the Z protein not only contains less sialic acid but also contains smaller amounts of the other carbohydrates than the M protein. Based on the established structures of the two oligosaccharide units present in the M protein, it seems that there are four oligosaccharide units in the M protein and three in the Z protein. We have also observed that the amino acid composition of the Z protein has a higher amount of glycine and arginine than that of the M protein. It is possible that this difference in amino acid sequence affects the attachment of the carbohydrate side chains, leading to a difference in the rate of secretion of the M and Z proteins which is ultimately responsible for the low concentration of the circulating Z protein in individuals with severe α_1-protease inhibitor deficiency.

The α_1-protease inhibitor was isolated from individuals of genetic type MM and ZZ and purified as before[5] and the genetic typing[6] was determined by two-dimensional electrophoresis. Since no change in the electrophoretic pattern of either protease inhibitor was observed before or after purification, the procedures for isolation did not alter the protein molecule. The isolated products were free of albumin and orosomucoid as shown by immunodiffusion on agar plates, and were homogeneous when subjected to disc electrophoresis on polyacrylamide gel[7] at *p*H 8.9 or 7.0. Results to be published in full elsewhere show that the M protein has a molecular weight of 54,000 and consists of a single polypeptide chain with four carbohydrate side chains of two structural types. The first type consists of four residues of N-acetylglucosamine, three of mannose, three of galactose and three of sialic acid. The second type consists of three residues of N-acetylglucosamine, three of mannose, two of galactose and two of sialic acid. These two types of oligosaccharide unit are present in equal amounts in the M protein.

Table 1 Comparison of the composition of amino acids and carbohydrates of the M and the Z α_1-protease inhibitor

	mol per 54,000 of protein	
	M	Z
Aspartic acid	43	42
Threonine	33	29
Serine	27	27
Glutamic acid	54	51
Proline	19	19
Glycine	22	30
Alanine	27	27
Valine	24	24
Half-cystine	ND	ND
Methionine	9	9
Isoleucine	18	16
Leucine	44	43
Tyrosine	6	6
Phenylalanine	28	26
Lysine	37	33
Histidine	12	13
Arginine	8	12
Tryptophan	ND	ND
N-acetyl-D-glucosamine	13	11
D-mannose	12	8
D-galactose	9	6
Sialic acid	9	5

Samples of α_1-protease inhibitor were hydrolysed in the following conditions: for amino acids, 6 N HCl at 110 °C *in vacuo* for 48 h; for N-acetyl-D-glucosamine, 4 N HCl at 100 °C *in vacuo* for 6 h; for neutral sugars, D-galactose and D-mannose, 1 N H_2SO_4 in sealed tubes for 8 h at 100 °C and for sialic acid, 0.18 N H_2SO_4 at 80 °C for 1 h. Amino acids and D-glucosamine were analysed on a Technicon automated amino acid analyser[10], whereas the neutral sugars were determined on an automated sugar analyser according to Lee *et al.*[11]. Sialic acid was determined as described by Warren[12]. Norleucine was used as an internal standard for analysis of amino acids and D-glucosamine, and D-xylose was used for D-galactose and D-mannose. ND, not determined.

Table 1 shows that the mannose content in the Z protein is approximately three-quarters of that of the M protein and suggests that the Z protein contains three instead of four carbohydrate side chains. Indeed, the Z protein contains roughly four sialic acid residues fewer than does the corresponding M protein. This result is consistent with the speculation of Bell and Carrell[2] and Cox[3]. The difference in sialic acid residues, however, does not necessarily explain the low concentration of the α_1-protease inhibitor in circulation since it is the exposure of the non-reducing terminal galactosyl residues that provides a means by which the liver recognises and removes asialoproteins[8,9]. Thus, even though the M and Z proteins differ in the number of galactosyl and sialic acid residues, as we have shown, the number of exposed galactosyl residues between the two proteins is essentially the same. If, however, the efficiency in the secretion of liver protein depends on the number of carbohydrate side chains, it is conceivable that the extra carbohydrate chain present in the M protein facilitates its secretion and thus maintains its concentration at the normal level.

Table 1 also compares amino acid composition between the M and Z protein. Because of the relatively large molecular weight of the protein, the data are more difficult to interpret. There was minimal difference (±10%) between the two homologous proteins, except that the Z protein had a significantly larger amount of argininyl and glycyl residues. In this case, the M protein would have been expected to be more negatively charged than the Z protein. This is verified by comparing the electrophoric mobilities of these two proteins and their corresponding asialoproteins. The mobility of the Z protein toward the anode was considerably slower than that of the M protein. After the removal of the sialic acid residues by digestion of the proteins with neuramidase (5% by weight) at 38 °C for 16 h, the electrophoric mobilities of both proteins were retarded, but the asialo Z protein maintained a slightly slower mobility than the asialo M protein, consistent with the amino acid composition data shown in Table 1.

This research was supported by a grant from the National Institutes of Health. We thank Drs R. Talamo and J. Pierce for performing the electrophoresis in their laboratories and for providing serum from ZZ individuals.

Non-random occurrence of 7–14 translocations in human lymphocyte cultures

SOMATIC cells dividing *in vitro* occasionally show chromosome recombination between non-homologues, most often in situations associated with an increased frequency of chromosome breakage and reunion[1,2], their occurrence being recognised by the observation of exchange figures. With the advent of new techniques for chromosome identification[3], it is now possible to identify the chromosomes involved in these rearrangements and to recognise some translocations which might otherwise be missed.

We have observed about 5,000 trypsin-banded[4] metaphases, from 250 individuals, among which a total of 9 cells seem to have a *de novo* balanced translocation. (The 'true' denominator needed to determine the percentage of abnormal cells of this type is necessarily imprecise, since in the course of scanning a preparation, attention may be drawn to a somewhat imperfectly banded metaphase with a morphologically abnormal chromosome and/or a unique banding pattern.) These translocations seem to be non-random, since three of the nine abnormal cells involved a translocation between chromosomes 7 and 14 (Fig. 1). These three cells were noted in three different individuals, studied for disparate reasons: one had Rubinstein–Taybi syndrome, one had multisystem nonspecific congenital anomalies and one was the healthy father of an infant with trisomy 22.

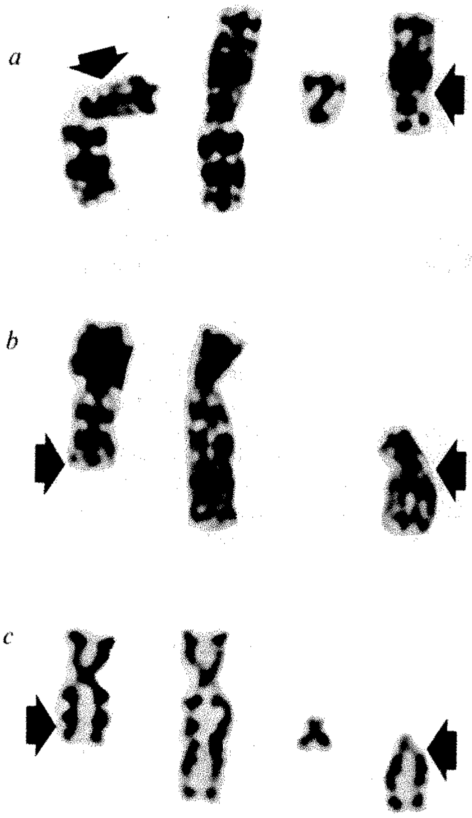

Fig. 1 Partial karyotypes of the three individuals found to have 7–14 translocations. The arrows indicate the breakpoints believed most likely for the number 7 and 14 chromosomes (see text). Note that there was no residual small acrocentric present in cell *b*. (Cell *c* was noted after routine Giemsa staining: it was subsequently destained and trypsin banding carried out.) The chromosomes have been arranged to match homologous segments whenever possible.

All three 7–14 translocations arose in short term (72-h) lymphocyte culture and the breakpoints of the number 14 chromosomes all seemed to involve the same region, q1(1–2). The breakpoints of the number 7 chromosomes were more variable (Fig. 1); cell *a* being 7p13; *b* 7q3(3–6); *c* 7q3(4–6). In two of the other six translocation lymphocytes noted in this study, a 7 or 14 chromosome was also involved; these were 46,XY, t(2;14)(p11;q32) and 46,XX, t(7;10)(q11–22; q2(4–6)). None of the preparations containing a *de novo* translocation showed any suggestion of an increased frequency of chromosome breakage.

It seems clear from these results that translocations between chromosomes 7 and 14 arise much more frequently during *in vitro* culture than would be expected on a random basis. This finding is corroborated by results in the two following papers[5,6] in this issue. The culture time allows for the possibility that the breakage and reunion may be an *in vitro* phenomenon only, and although the circumstances suggest that it is not likely to be a result of mycoplasma infection, a viral aetiology cannot be excluded.

The breakpoints involved in somatic *de novo* 7–14 translocations seem to be relatively specific. Combining these data with those of Beatty-DeSana *et al.*[5] and Hecht *et al.*[6], we note that the 14q1(1–2) region is involved in all twelve somatic 7–14 translocation cells observed, together with the 7q3(3–6) region in six of these and the 7p13 region in the remainder. None of these breakpoints occurred in the 2–14 and 7–10 single cell translocation noted above. Further, although chromosome 14 is commonly involved in human meiotic translocations[7-9], meiotic 7–14 translocations seem to be uncommon and those reported previously[10,11] involve breakpoints other than those above.

Our observations could be a result of an increased tendency to breakage in certain regions of chromosomes 14 and 7, together with the relative proximity of these chromosomes during somatic replication. The latter may be associated with the residua of ancient homology between heterologous chromosomes[12] and we think that there is some resemblance between the 14q and 7p banding patterns. This theory would suggest an increased number of 7–14 exchanges following lymphocyte irradiation, however, but this does not occur[13-15].

Similar 7–14 translocations occurring in proliferative clones[6] have been noted in ataxia-telangiectasia[1,6], a condition often associated with lymphoid neoplasia. Because of the rarity of meiotic 7–14 translocations and the known association of another relatively specific somatic translocation with chronic myeloid leukaemia[16], we wonder whether these observed 7–14 somatic translocations may also have an increased malignant propensity.

This study was assisted by funds provided by a Public Health Research Grant of the Canadian National Health Grants program.

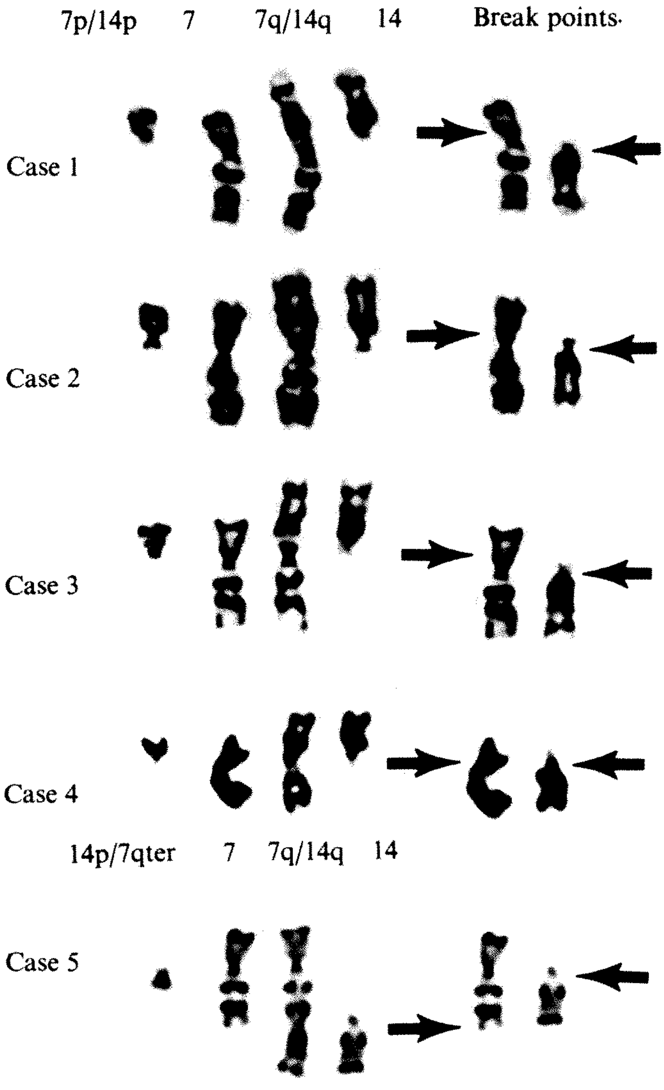
CYTOGENETIC studies of human lymphocytes cultured from patients and their families using known banding methods [1-2] provide an opportunity to observe spontaneous chromosomal aberrations, to identify the chromosomes involved in a rearrangement and aid in interpreting the cytogenetic events leading to their formation. In our investigations of many high risk families over a 4-yr period, all breaks, fragments and rearrangements noted in the lymphocyte cultures were recorded, along with the total number of cells counted because of previous experience in the study of X-ray induced chromosomal aberrations[4,5]. The observations reported here are from 72-h cultures, which may complicate their interpretation[6,7] since they are subject to the selective advantages or disadvantages of a particular chromosomal rearrangement and other factors. The many variables inherent in the analysis preclude rigorous statistical treatment of these data, but a general description of the nature of occurrence may be helpful.

Studies of 25 lymphocyte metaphases each are from 852 consecutively karyotyped mentally retarded people and their families, together with others serving as controls in various studies. Five unrelated people aged less than 40 with normal karyotypes (three with nonspecific mental retardation and two normal, first-degree relatives of people with chromosome anomalies) were found to have a single cell containing a reciprocal translocation between chromosomes 7 and 14. The apparent break point was at 14q1(1–2) in all five, and at 7p13 in four and 7q3(4–6) in the fifth (Fig. 1)[8]. Amplification of the pale band at the region where the two breaks are thought to have joined in the large translocation chromosome indicates that the break is at the edge of the pale band in each chromosome, so that region 7p13 (or 7q3(4–6) in one translocation) is now adjacent to 14q11. We found a total of 42 two-break rearrangements (1 in 500 cells) including dicentrics and rings—usually with accompanying fragments—translocations and exceedingly rare chromatid exchanges. With the exception of the 7–14 translocation, no other consistent aberration was found. Three others, however, involved D-group chromosomes, two dicentrics with fragments, and a 13–14 translocation, all three of which had breaks seemingly in the 14q11 and telomere regions. The consistent translocations have been found once every 8–10 months during the past 4 yr. No infection of cultures or contaminant of the culture media is suspected.

A sample of 25 cells from a single human represents only 2×10^{-9} of the total lymphocyte population[9]; thus the nonrandom occurrence of a 7–14 translocation in a single cell of five individuals, not known to have any malignancy or any

Fig. 1 Sporadic reciprocal translocations involving chromosomes 7 and 14 in human lymphocytes.



suggestion of a predisposition to increased chromosome breakage, indicates that this may be a phenomenon more widespread in routine lymphocyte cultures than is now known. Studies from other cytogenetics laboratories reported in this issue[10,11] provide similar findings which confirm these results. The similarity of these aberrant chromosomes indicates a specificity of breakage points which suggests that their presence is significant and that one or more of the following factors may be involved: A specific aetiological agent[12]; some selective advantage[13] conferred by the translocation; a genetically-based alteration of the repair mechanism[14]; or the spatial arrangement of the chromosomes in the cell. The true significance of these translocations awaits further study.

WE report here the occurrence of somatic chromosome translocations in lymphocytes from individuals studied for clinical cytogenetic diagnosis. We note that these translocations are non-random in composition and resemble those in ataxia-telangiectasia (A-T) lymphocyte clones[1]. Our data have been collated with information from two other centres (Halifax and Atlanta) reported in this issue[2,3], to provide a preliminary estimate of the frequency of chromosome translocations in cultured lymphocytes.

Our sample consisted of 6,000 lymphocyte metaphases; 20 from each of 300 consecutive patients or relatives referred for genetic counselling. None was known to have a chromosome instability syndrome, malignancy, or unusual X-ray or drug exposure. Lymphocytes were cultured with phytohaemagglutinin (PHA) for 68–72 h and harvested with colchicine. Metaphases were Giemsa-banded, selected under low power microscopy and photographed. Karyotypes were prepared from two or more cells per person[4].

Four of the 6,000 cells were found to contain a chromosome rearrangement and each of the four was from a different person. Each rearrangement was a translocation between chromosome 7 and 14 (Fig. 1). Three involved the q33–35 region and one the p13 band of chromosome 7. The breakpoints in chromosome 14 were consistently in band q12.

The chromosome rearrangements in this study resemble those observed in A-T lymphocytes. Lymphocyte clones from 22 A-T patients have been detected, each with a translocation. These A-T translocations involve a D chromosome, identified as No. 14, with the breakpoints in band 14q12. The other chromosome in the A-T translocation is often a No. 7 with the breakpoints (ref. 1 and B.K.M., F.H., D. G. Harnden and R. Teplitz, ref. 8) in p13 or q33-35, as in our study. These data suggest that in lymphocyte somatic chromosome rearrangements there is non-random involvement of chromosomes 7 and 14.

Table 1 Frequency of translocations in cultured human lymphocytes

Locale	Individuals	Lymphocytes	All translocations No. (freq.)	7–14 translocations No. (freq.)
Halifax	250	5,000	9 (1/556)	3 (1/1667)
Portland/Denver	300	6,000	4 (1/1500)	4 (1/1500)
Atlanta	852	21,300	42 (1/507)	5 (1/4260)
Total	1,402	32,300	55 (1/587)	12 (1/2692)

From our study and those reported in this issue (refs. 2,3 and Table 1) the frequency of *de novo* chromosome translocations in cultured lymphocytes is calculated to be roughly 1.7×10^{-3}. The frequency of 7–14 translocations is roughly 4×10^{-4}. These are crude estimates, since the sample size is relatively small and subtle rearrangements may have been missed.

By comparison, it is interesting that the mutation rate for structural autosomal rearrangements in germ cells resulting in live births has been estimated to be in the same range, about 4×10^{-4} (ref. 5). It is also interesting that meiotic translocations in humans are generally non-random in composition. For example, D/D translocations are largely of the 13–14 type[7] and D translocations in patients with Down's syndrome tend preferentially to be of the 14–21 type[6,7].

The basis for the non-randomness of somatic chromosome rearrangements is open to conjecture. It must reflect a preferential pattern of rearrangement and/or selection for lymphocytes with 7–14 translocations. The repositioning of genetic material ('position effect') presumably may alter the expression of genes and thus change cell behaviour and function in some as yet unexplained manner.

Fig. 1 Translocations in lymphocytes cultured from four individuals (*a*–*d*). The arrow on the left indicates the point at which the distal part of chromosome 14 is translocated to the long arm (*a*–*c*) or to the short arm (*d*) of chromosome 7. The arrow on the right indicates the breakpoint in chromosome 14.

The biological meaning of these translocations in lymphocytes is not yet clear. They may occasionally we believe (B.K.M., F.H., D. G. Harnden and R. Teplitz, ref. 8), represent an early tentative step towards the eventual development of lymphoid malignancy.

Factor suppressing α-foetoprotein production in newborn mice

α-FOETOPROTEIN (AFP) is one of the main proteins of embryonic serum. Its synthesis begins in the yolk sac, continues in embryonic liver and terminates, in mice and rats, at the beginning of the postnatal period[1,2]. Presumably, a powerful suppression factor acts on AFP production by embryonic liver cells after the embryonic period has finished. The present study was undertaken to determine this factor(s).

Families of newborn BALB/c mice were divided into two groups. One group was injected daily with serum or extracts of various organs of syngeneic adult mice and embryos, and the other was untreated. After 10 d, the AFP titre was determined in the serum of each group of newborn mice. Extracts of small intestine were used because, during embryogenesis, the liver is formed out of the small intestine and various endocrine connections may persist between these two organs.

Extracts (see Table 1) were injected into the skin of the back of newborn mice, the volume of the material injected increasing as the animals grew older. From day 1 to the day 4 of life, mice were inoculated with 0.1 ml, on days 5 and 6 with 0.2 ml, on day 7 with 0.3 ml, on days 8 and 9 with 0.5 ml. Newborn mice were injected, according to the same schedule, with sterile serum from adult mice. Each mouse killed on the day 10 had received 2.1 ml 20% extract. The AFP titre of controls receiving only Hanks' solution was not affected (Table 1).

Microprecipitation in agar was performed as described previously[3]. Mouse serum was diluted from 1:2 to 1:1,024. This test system (1:2) was used with the above dilutions of the sera from newborn mice and the results determined on the following day (Fig. 1*a*). Test system: (1) antigen–serum of newborn mice; (2) antiserum–the monospecific serum of rabbits immunised with purified α-foetoprotein.

It is evident from Table 1 that in the serum, in the small and large intestine, liver, lung, brain, thymus, spleen and kidneys of adult mice there is a factor(s) suppressing AFP production in neonatal mice. Figure 1*b* and *c* show the AFP-suppressing effect of the extracts of small intestine. Extracts of 21-d-old mouse intestine produced a weaker effect than those of the adult. The factor is hardly detectable in small intestine of mice embryos, in the whole embryo or in striated muscles of adult mice. Heating of the small intestine extract at 60 °C for 45 min inactivated the suppression mechanism (data not shown). This high thermolability probably indicates the protein nature of the factor.

The function of embryonic antigens in tumour cells and the factors controlling their appearance remain obscure. Growth of tumours and transplants of foetal digestive tract is inhibited in newborn mice[4,5], and it may therefore be anticipated that suppression factor(s) controlling the synthesis of embryonic antigen are produced in the embryonic body, but are absent in

*Reciprocal to last dilution of serum of newborn mice in which AFP is determined in the microprecipitation test.

†Serum AFP titre of the experiment and control was the same, although the intensity of the precipitation line in the control was a little more distinct than in the experimental half.

The upper part (8 cm) of the small intestine was excised from adult BALB/c mice and its contents evacuated. It was then sectioned, washed repeatedly with Hanks' solution containing antibiotics (1000 U penicillin and streptomycin ml^{-1}), incubated in this solution for 30 min at 37 °C, and then washed repeatedly with Hanks' solution without antibiotics. The tissue was carefully ground in a mortar with glass powder; 20% extracts (20 g tissue 100 ml^{-1} Hanks' solution were prepared with 200 U ml^{-1} penicillin and streptomycin, and the homogenate centrifuged at 500 r.p.m. for 5 min. The supernatant was poured into plastic ampules and stored in liquid nitrogen (−196 °C) for 18 h, and subsequently at −22 °C. When required, ampules containing extracts were thawed and used for injections. Sterile extracts from liver, kidney, lung, brain, striated muscle and large intestine were prepared using this technique. Extracts were also prepared from small intestine of 21-d-old mice and mouse embryos taken at the end of the period of pregnancy. Extracts were also prepared from whole mouse embryos (head included) but with the gastrointestinal tract excised.

adults. Using the suppression factor(s) from embryos or adults regulating induction and repression of antigens in normal embryonic cells, it might be possible to affect tumour cells synthesising the same embryonic antigens. These regulating factors were previously unknown, but one is possibly described here. Whether such a factor suppresses AFP synthesis in embryonic liver cells or the multiplication of the cells producing AFP, remains obscure. It seems possible that it would first normalise hepatoma cells, and then inhibit their multiplication. The detection of this suppressing factor seems to confirm the following general approach. Suppression factors affecting the synthesis of a given embryonic antigen must be determined in an organism by starting with that stage of ontogenesis in which their synthesis terminates, and sometimes after this stage. The systematic search for new hormones of embryonic and especially late embryonic and early postnatal periods would be particularly relevant.

We thank Dr F. J. Rauscher Jr for some research materials; Drs A. K. Jazova, A. I. Gousev and A. R. Karamova for the test system; and Drs H. I. Abelev and L. N. Fontalin for discussions.

Evidence against clustering of thymine dimers in ultraviolet-irradiated DNA

IRRADIATION of DNA with ultraviolet light causes chemical and physical alterations. From the chemical point of view the main effect of 254 nm UV light is the formation of pyrimidine dimers. The physical consequence of this is a destabilisation of the DNA double helix, presumably by formation of small denatured regions (defects).

According to Shafranovskaya *et al.*[1], the number of defects as determined by the kinetic formaldehyde method is approximately equal to the number of thymine dimers at low fluences of ultraviolet light, but increases much less rapidly than the yield of dimers at fluences above 10 J m^{-2}. To explain these results they assume that at low fluences every dimer produces a defect, but that at higher fluences dimers are preferentially formed at pre-existing defects after migration of the excitation energy over large distances, up to several thousands of base pairs.

To check this important hypothesis we repeated the experiments of Shafranovskaya *et al.*[1] very carefully taking every precaution to prevent artefacts. Contrary to their findings the concentration of defects did not depart significantly from a linear dependence on ultraviolet fluence. Our experiments therefore contradict the assumption of large distance energy transfer in DNA but of course do not exclude the possibility of energy migration over short distances.

The theory of the kinetic formaldehyde method[2,3] predicts that denaturation of DNA by the action of formaldehyde follows the equation

$$(-\ln\theta)/t = p\nu + 2vc + pvt \qquad (1)$$

in which c is the initial number of defects per base pair, v the rate of reaction of formaldehyde with base pairs at the boundary of a defect, p the rate for reaction with base pairs in a stable helix and ν the average number of base pairs opened up together in the latter process. Under suitably chosen conditions the term $p\nu$ can be neglected. The degree of helicity θ is defined as

$$\theta = (A_f - A)/(A_f - A_i),$$

where A_i, A and A_f are the initial absorbance, the absorbance at time t and the final absorbance, respectively.

Plotting $(-\ln\theta)/t$ against t gives a straight line with a slope pv and an intercept $2cv$ on extrapolation to $t=0$, and c can be calculated if v is known.

The quotient $(-\ln\theta)/t$ is rather sensitive to errors in A_i. Because the absorbance at the time of mixing of DNA and

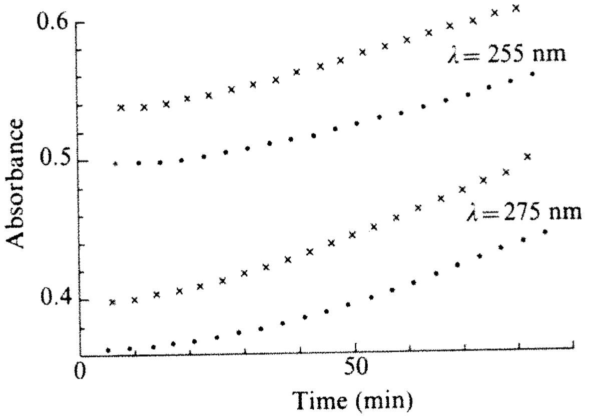

Fig. 1 Change in absorbance of DNA under the action of formaldehyde: ●, non-irradiated DNA; ×, DNA irradiated with 66 J m^2 (see legend to Fig. 3). Solvent for DNA was 0.01 M borate buffer, *p*H 8.7, containing 0.019 M NaCl and 5×10^{-4} M EDTA (ref. 3). Formaldehyde was prepared from paraformaldehyde[5], kept at 100 °C for 5–10 min[6], neutralised and taken up in concentrated buffer solution to obtain a concentration of 6.7% (w/v) in the same solvent as used for DNA. The final solution was kept at room temperature for at least 2 d to eliminate undesirable drifts in absorbance. Equal weights of DNA and formaldehyde solution were brought into both halves of a two-compartment spectrophotometer cell, equilibrated at 47.5 °C for 60 min and then mixed. During the mixing and subsequent measurements the temperature in the cell remained constant within 0.02 °C. The transmission of the reaction mixture was measured as a function of time in a Zeiss PMQ II spectrophotometer connected with a digital voltmeter to improve the sensitivity. At 90 min after mixing the temperature of the cell holder was increased to 70 °C for 10 min to complete the reaction and then brought down again to determine the final transmission.

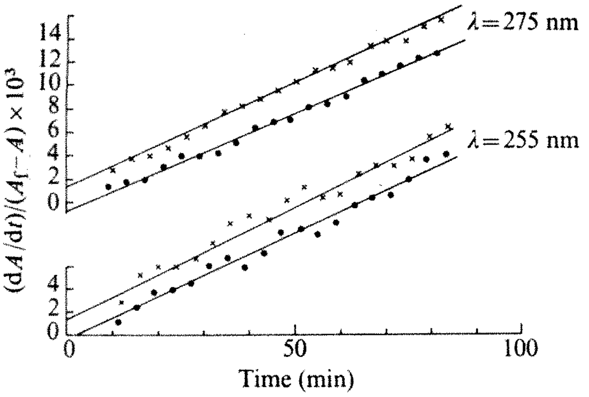

Fig. 2 The kinetics of the reaction of formaldehyde with T2-DNA at 47.5 °C presented as a plot of $(dA/dt)/(A_f-A)$ against t at wavelengths of 255 and 275 nm. ●, non-irradiated DNA; ×, DNA irradiated with 66 J m^{-2}.

formaldehyde cannot be determined very accurately we analysed our data by computer using the equation

$$(dA/dt)/(A_f-A)=2vc+2pvt \tag{2}$$

which is in fact the differential equation on which equation (1) is based. The relevant quantity $2vc$ is obtained in the same way as with equation (1), that is, by determining the intercept of a straight line at $t=0$.

The experiments were performed with DNA from the same bacteriophage, T2, as that used by Shafranovskaya *et al.*[1]. In this DNA the only pyrimidine dimers produced are thymine dimers. Figure 1 shows the change in absorbance of DNA caused by the action of formaldehyde. All measurements were carried out at 255 and 275 nm, the first wavelength being that of the isosbestic point for the reaction between formaldehyde and denatured DNA. Here the absorbance change is only caused by DNA denaturation, whereas the (larger) change at 275 nm contains a contribution from the formaldehyde reaction itself.

Examples of plots according to equation (2) are given in Fig. 2 for non-irradiated DNA and DNA irradiated with 66 J m^{-2}. The fact that the slopes for both wavelengths do not differ significantly confirms the expectation that reaction with formaldehyde goes hand in hand with denaturation. The wavelength of measurement is therefore not very critical. For reasons as yet unknown, the value of $2vc$ for non-irradiated DNA is slightly negative.

Figure 3 shows that the concentration of defects in DNA increases in proportion to ultraviolet fluences from 0 to 165 J m^{-2}.

These results together with their standard errors are summarised in Table 1. The figures obtained from plots of $(-\ln\theta)/t$ (using extrapolated values of A_i) are also given. Although they are somewhat less reliable, they seem to lead to the same conclusion.

We are unable to indicate exactly why our experiments show a linear dependence of $2vc$ on ultraviolet fluence, whereas those of Shafranovskaya *et al.* do not. It should be stressed, however, that without careful precautions erroneous and irreproducible results may be obtained because the change in absorbance after mixing may be caused partly by factors other than the reaction of DNA with formaldehyde. First, the temperature must be kept constant within narrow limits. Second, the absorbance of formaldehyde shows a slow drift after a change of temperature, the effect of which is largely eliminated by special pre-equilibration procedures (Fig. 1). Third, it seems that without the pre-equilibration procedures the absorbance of formaldehyde showed a slow drift after mixing with an equal volume of buffer. Fourth, imperfectly cleaned cells sometimes showed a slowly varying blank absorbance.

To check whether the dose–effect curve is linear one does not need to know the value of v. This value was obtained by Shafranovskaya *et al.* by calibrating the kinetic formaldehyde method using single- or double-strand breaks in DNA as defects, the number of which can be determined by ultracentrifugation. Rahn and Stafford[4] produced evidence that for dimer defects the value of v is much smaller than for break defects. This may explain why at high doses the number of defects seems to be much smaller than the number of dimers, determined by chromatographic techniques. The evidence of Rahn and

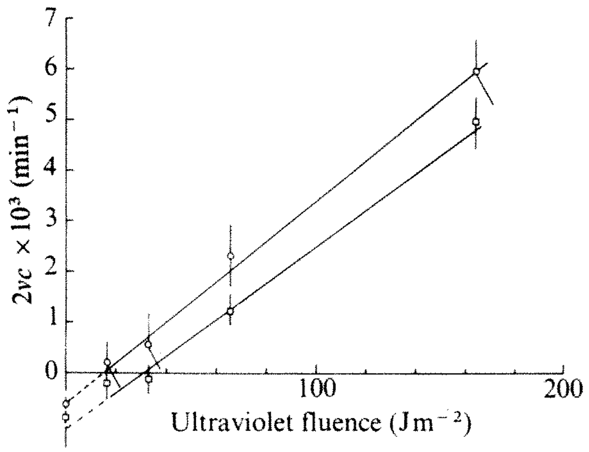

Fig. 3 Relative concentration of defects (value of $2vc$) in T2-DNA as a function of ultraviolet fluence: ○, measurements at 255 nm; ☐, measurements at 275 nm. Irradiations were carried out with a 15 W low pressure mercury lamp. Solutions (absorbance 0.4) were irradiated horizontally in silica spectrophotometer cells with a light path of 1 cm and containing a small magnetic stirrer. The lamp output was monitored with a Yellow Springs Instrument–Kettering radiometer. The intensity at the position of the cell was 0.65 J m^{-2} s^{-1} and was derived from the inactivation rate of T4 and øX174 phage assuming 37% survival at 2.83 and 8.07 J m^{-2}, respectively[7,8]. The experimental points for irradiated DNA are the weighted averages of two or three measurements. The straight lines were obtained by least squares analysis of all these points. Each of the two points for non-irradiated DNA is the weighted average of seven measurements. Bars represent s.e.

Table 1 Analysis of the measurements*

Calculation number	Wavelength (nm)	$2vc_0\times10^3$ (min^{-1})	Irradiated DNA Intercept × 10^3 (min^{-1})	Slope × 10^3 (min^{-1}J^{-1}m^2)
A	275	−0.9±0.1	−1.1±0.2	0.036±0.003
	255	−0.7±0.2	−0.5±0.2	0.040±0.003
B	275	−0.5±0.2	−0.5±0.9	0.03±0.02
	255	−0.1±0.2	−0.1±1.2	0.03±0.02

*Kinetic curves were analysed using one of the formulae (1) and (2) from the text. The data under A were obtained using equation (2), the data under B using equation (1). From the seven measurements for non-irradiated DNA, a weighted average $2vc_0$ was calculated (c_0: the concentration of defects at zero UV fluence). The values of $2vc$ at ultraviolet fluences between 16 and 170 J m^{-2} were fitted by a straight line (Fig. 3); the intercept and the slope of this line are given. The intercept does not differ significantly from $2vc_0$.

Stafford together with our linear dose–effect relationship makes it very unlikely that the hypothesis of clustering of thymine dimers through long range energy migration is correct.

We thank Messrs J. B. Verberne and J. W. Niemantsverdriet for assistance.

Assembly of DNA and protein during replication in HeLa cells

REPLICATION in eukaryotic cells includes not only DNA synthetic processes[1-4], but also the temporally coordinate[5-7] and non-coordinate[8,9,21] synthesis of chromatin proteins, as well as assembly of these constituents into interphase chromosomes. While much is known about DNA, histone and non-histone chromatin protein biosynthesis, less is known about the time, place and manner of association of proteins with DNA. This communication presents evidence that (1) DNA is replicated with pre-existent chromatin protein still attached; (2) chromatin proteins protect DNA from nuclease digestion in a characteristic manner, unchanged by replicative processes, and (3) addition of new chromatin protein to nascent DNA occurs after a measurable lag period.

Nuclease digestion was used as a probe to examine the extent of DNA-protein associations. Two nucleases are well characterised in chromatin degradations: (i) pancreatic DNase I digests chromatin in a biphasic manner in which DNA is quantitatively degraded, the reaction rate being dependent on the enzyme-substrate ratio[10,11]; (ii) staphylococcal nuclease ceases digestion after hydrolysis of 45–50% of chromatin DNA (limit digest) irrespective of enzyme load[11,12,16,22]. Since the two nucleases behave so differently with chromatin, I used each enzyme in parallel digestion studies to ensure that the data were qualitatively in agreement and were not produced by anomalous interplay of either enzyme with the complex deoxyribonucleoprotein substrate.

To study the timing of addition of protein to chromatin, newly synthesised DNA was assayed for nuclease susceptibility. Cells were incubated with ^{3}H-thymidine for periods of 30 s to 32 min, or 12 h for controls (Fig. 1). The kinetics of DNase I digestion of nuclei prepared from each incubation are given in Fig. 1. The most briefly labelled DNAs (30 s–1 min ^{3}H-thymidine) were substantially more accessible to nuclease attack than control chromatin, being intermediate between values for free DNA (>95% degradation) and control chromatin. This enhanced susceptibility was of brief duration, for resistance to digestion increased with the duration of the labelling period, finally to the level of control chromatin within 10-20 min. In Fig. 1*b* the results are plotted as the amount of each sample digested in 45 min as a function of labelling period, to illustrate more clearly the kinetics of maturation of nuclease resistance. These results are qualitatively the same with both DNase I and staphylococcal nuclease.

That the progression of nuclease-susceptible nascent DNA

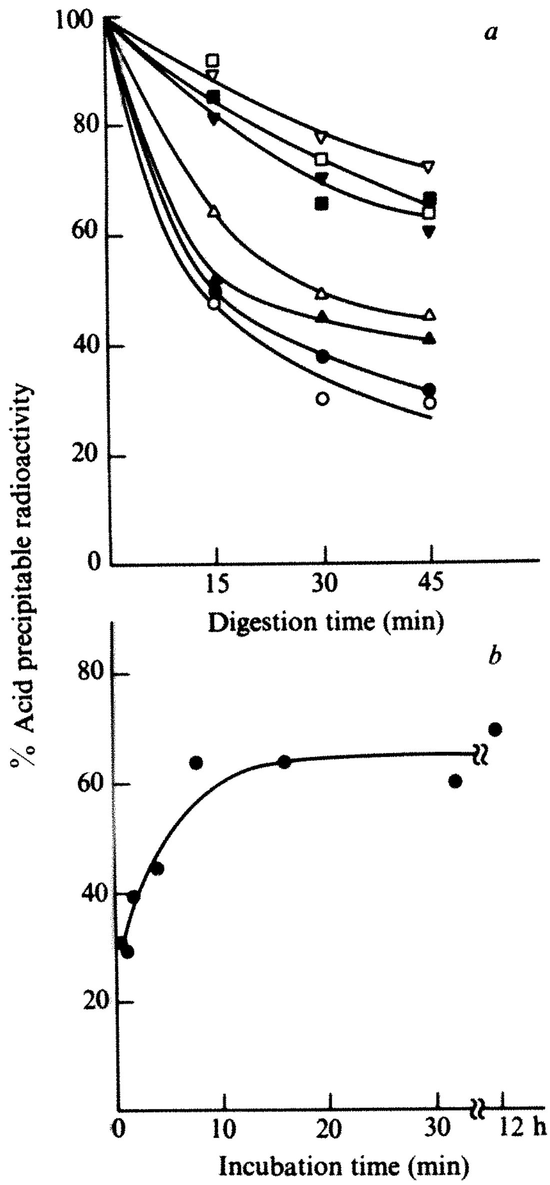

Fig. 1 *a*, Kinetics of DNase I digestion of nuclei labelled for 0.5 (●), 1 (○), 2(▲), 4 (△), 16 (□), and 32 min (■), and for 12 h (▽) with thymidine. *b*, Nuclease resistance of labelled chromatins after digestion for 45 min. Note different abcissas in *a* and *b*. HeLa S-3 cells, maintained at $2–5\times10^5$ ml^{-1} in Eagle's MEM containing 5% horse serum were concentrated to 2×10^6 ml^{-1} for labelling. Samples (20 ml) of concentrated cells were incubated with 200, 200, 150, 100, 50, 25 and 10 µCi ^{3}H-thymidine (6.7 Ci mmol^{-1}) for 0.5, 1, 2, 4, 8, 16 and 32 min respectively. Control cells were labelled for 12 h at 0.01 µCi ml^{-1}. Labelling was terminated by immersion of the tube in ice and addition of 2 volumes of RSB (10 mM Tris-HCl, *p*H 7.6, 1.5 mM $MgCl_2$, 10 mM NaCl) containing 0.2% sodium azide. The cells were collected by centrifugation at 1,800*g* (maximum) for 1 min. The pellet was resuspended and washed again in 20 ml RSB. After resuspension in RSB the cells were swollen for 10 min and then 0·1 volume 10% Triton X-100 was added. The cells were swirled on a Vortex mixer for 30 s and then centrifuged at 1,800*g* for 1 min. The nuclei were washed twice more in RSB. The final nuclear suspension in RSB was adjusted to a concentration of 3.0 A_{260} units ml^{-1}, as measured in 1% sodium dodecyl sulphate. Samples (0.1 ml) of the nuclear suspension were added to tubes, followed by 0.8 ml RSB. Then, 5 µg DNase I (Worthington) in 0.1 ml RSB was added and, after mixing, the tubes were placed in a 37 °C water bath. At the indicated times, reactions were stopped by placing tubes in ice and adding 2 ml 10% trichloracetic acid. Samples (100 µg) each of bovine serum albumin and calf thymus DNA were added to each tube and the precipitates were collected on Whatman GF/C filters. To each filter, 0.2 ml of a 9:1 NCS (Amersham/Searle)–water mixture was added, followed by 10 ml of 0.4% PPO in toulene. Vials were incubated for 12-16 h at 37 °C before counting in a Beckman LS-250 liquid scintillation spectrometer.

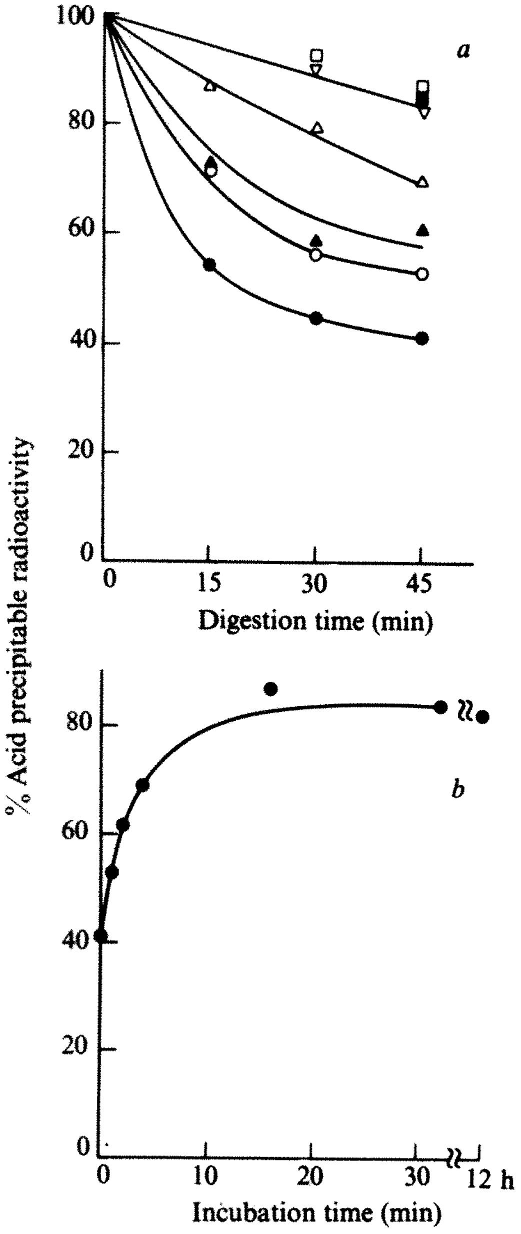
to the relatively nuclease-resistant control chromatin represented a true precursor–product relationship, was demonstrated by labelling nascent DNA by brief incubation with isotope, and following the fate of the incorporated radioactivity after removal of isotope (Fig. 2). Cells were incubated with ^{3}H-thymidine for 90 s and, after removal of isotope, samples were collected at intervals for 30 min. The nuclease resistance of the 90 s labelled material was again 50% that of controls. Resistance of the radioactive DNA to digestion increased progressively with time to reach controls after 10–15 min of further incubation. That the digestibility of the first sample taken after labelling was already less than the 90 s sample, reflects the 5 min required for the washing procedure. There was no evidence that newly synthesised DNA was protected from nucleases, relative to controls, in contrast to a report on nuclease susceptibility of nascent DNA in chick erythrocyte chromatin[15]. The time for unidirectional synthesis of replicon-sized units (3.5–15 μm)[1] of DNA at chain elongation rates of 0.8–2 μm min^{-1} (refs 1, 3 and 18–20) is about 5–15 min. Thus the period of 10–15 min observed for maturation of nuclease resistance, interpreted to represent chromatin protein addition, corresponds with that for completion of replicons.

Fig. 2 Digestibility of briefly labelled chromatin DNA after removal of label. Cells, as described in the legend to Fig. 1, were incubated with 10 μCi ^{3}H-thymidine ml^{-1} for 90 s. To terminate labelling, non-radioactive thymidine was added to 50 μg ml^{-1}. A sample was removed for the initial sample and the cells were centrifuged at 1,800*g* (maximum) for 1 min. Cells were resuspended in 37 °C medium containing 50 μg thymidine ml^{-1}, centrifuged again, and finally resuspended in fresh thymidine-containing medium for the times indicated. Samples were collected and processed at the times indicated as described for Fig. 1. ●, ^{3}H-thymidine incubation for 90 s; ○, zero time after isotope removal; ▲, further incubation for 2 min; △, 4 min; ■, 16 min; □, 32 min; ▽, one generation label.



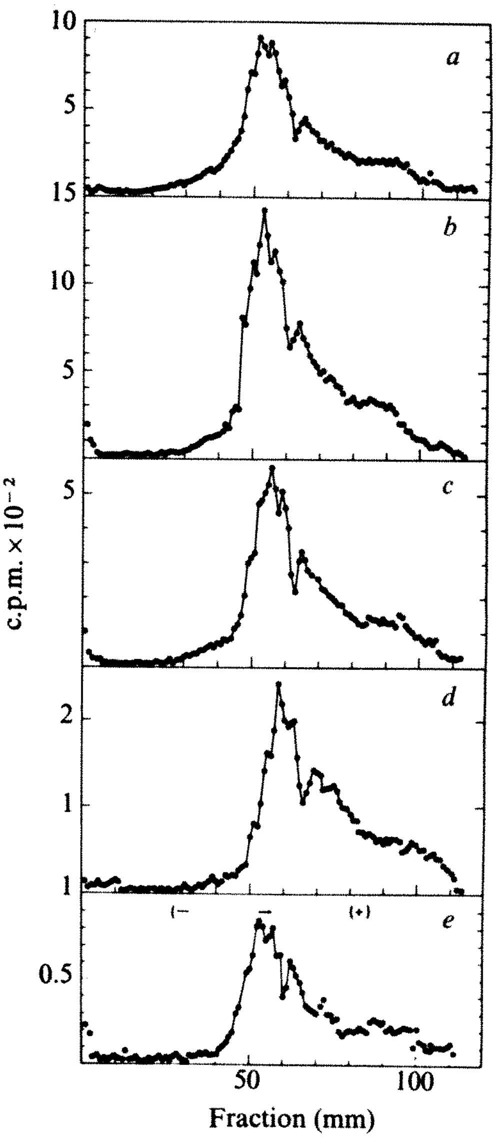


Fig. 3 Polyacrylamide gel electrophoresis of nuclease-resistant DNA fragments from staphylococcal nuclease limit digests. *a*, one generation label; *b*, 10 min; *c*, 4 min; *d*, 90 s; *e*, 45 s. Cells were incubated with 10 μCi ml^{-1} (*b*–*e*) or for 16 h with 0.01 μCi ml^{-1} ^{3}H-thymidine (*a*), respectively. Nuclear digestions were performed in 5 mM phosphate *p*H, 2.5×10^{-5} M Ca^{2+} with 1 μg of staphylococcal nuclease. After 90 min precipitates were collected by centrifugation at 17,000*g* for 10 min. The precipitates were dissolved in 1% SDS, 0.1 M NaCl, 1 mM EDTA, 10 mM Tris, *p*H 7.6, extracted three times with chloroform isoamyl alcohol (24:1), and precipitated with 2 volumes ethanol at –20 °C for 16 h. DNA was dissolved in electrophoresis buffer containing 6 M urea. The samples were applied to 0.6 × 10-cm 6% acrylamide gels (20:1 acrylamide-*bis* acrylamide) and were subjected to electrophoresis in buffer containing 0.089 mM Tris, *p*H 7.6, 0.90 M boric acid and 6.5 mM disodium EDTA [17] for 2 h at 2 mA per gel. Gels were scanned at 260 nm in a Beckman Acta III recording spectrophotometer equipped with a linear transport device. The gels were then fractionated into 1-mm segments with a Mickle Gel Slicer (Brinkmann Instruments). Gel slices were incubated in 0.5 ml NCS (Amersham/Searle)–water (9:1) at 50 °C, 12 h. Scintillation fluid was then added, and after 6 h at 37 °C counting was carried out as in Fig. 1.

Staphylococcal nuclease digestions produce a true limit digest of chromatin[11,21,22] and the resistant DNA can be resolved in polyacrylamide gels as a series of fragments of discrete sizes[16]. By this method, the size classes of resistant DNA from control chromatin were compared with patterns from briefly labelled chromatins as described in Figs 1 and 2 (Fig. 3). The patterns of nuclease-resistant DNA fragments derived from cells labelled for 45 s, 90 s, 2 min, 4 min, 10 min and 17 h were all the same. Recoveries from gels averaged 80-85% in all cases.

These results can be interpreted in the form of a simplified model. Chromatin is represented as DNA complexed with discrete protein oligomers[13,14], possibly of different, but a limited variety of sizes. As DNA is replicated, these protein oligomers segregate with the daughter chromosomes such that the newly synthesised DNA has half the protein content of mature chromatin. As replicon-sized DNA fragments are synthesised (about 10-20 min), new protein is added and nuclease resistance increases to that of parental chromatin. Because the size of nuclease-resistant DNA fragments is identical at all times, I propose that chromatin proteins (histones) associate with the new DNA in oligomeric form. Thus, all chromatin, regardless of the state of maturation and nuclease resistance, yields the same size classes of resistant DNA fragments.

I thank Dr R. Simpson, in whose laboratory this work was carried out, for advice and encouragemet. The late Dr H. A. Sober gave continuous interest and support.

Denaturation of polyoma DNA by phage T4 gene 32 protein

POLYOMA virus is a small oncogenic virus containing a circular DNA, the identification and location of defined regions of which provides physical reference points which are important for correlation in genetic and biochemical studies. The protein coded by gene 32 of bacteriophage T4 binds tightly to single-stranded DNA and RNA and facilitates denaturation and renaturation of double-stranded DNA[1,2]. Using glutaraldehyde fixation gene 32 protein denaturation of double-stranded DNA can be observed using electron microscopy at physiological temperatures, and denaturation maps are produced which closely resemble those obtained with heat and alkaline denaturation[2]. Use of gene 32 protein in binding experiments with circular supercoiled DNA molecules from polyoma virus and simian virus 40 (SV40) has already shown that only one denaturation loop is formed per molecule[2-4] reflecting possible structural constraints in the DNA. The characterisation and mapping of the preferred denaturation site(s)[4] is also of interest since these putative A+T-rich region(s) are likely to be related to the binding sites of enzymes using DNA as a template. In the present study the use of two different specific restriction enzymes (endonucleases) has enabled us to identify five regions of polyoma DNA which are preferentially denatured by phage T4 gene 32 protein, and the determination of their precise locations on the circular viral DNA.

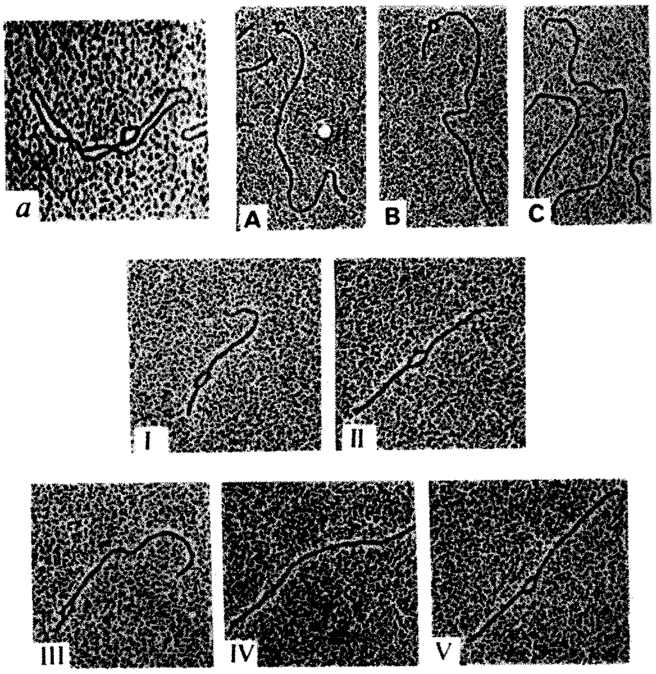

Fig. 1 Electron micrographs of polyoma DNA molecules carrying a denaturation loop induced by gene 32 protein. *a*, Closed polyoma DNA molecule carrying a denaturation loop. A, B and C, *Eco*RI cleaved polyoma DNA molecules carrying denaturation loop induced by gene 32 protein at three different sites. I and II, 43% fragment from *Hin*III digestion of Py DNA denatured by gene 32 protein with a denaturation loop at one of two sites. III-V, 57% fragment from *Hin*III digestion of polyoma DNA denatured by gene 32 protein with a denaturation loop at one of three sites. Gene 32 protein was purified from *E. coli* cells infected with an amber mutant of T4 bacteriophage (lysozyme⁻) obtained from the New England Enzyme Centre, Massachusetts, using the method of Alberts and Frey[1]. Polyoma DNA was labelled with ^{3}H-thymidine and extracted from cells infected with *A-2* strain of large plaque virus at low multiplicities of infection[5] by the method of Hirt[6] followed by phenol extraction, equilibrium centrifugation in CsCl–ethidium bromide, and purification by neutral sucrose density gradient centrifugation. Complexes of polyoma DNA (form I) with T4 gene 32 protein were prepared according to Delius *et al.*[2]. After fixation in glutaraldehyde the sample was dialysed against 0.01 M Tris-HCl, *p*H 7.4, containing 0.01 M NaCl and 1 mM EDTA at 4 °C, and concentrated. Conditions were then adjusted and digestion carried out with endonuclease *Eco*RI and *Hin*III as described by Griffin *et al.*[7]. The preparation of samples for electron microscopy was carried out as described by Davis *et al.*[8]. An internal length standard of PM2 DNA (taken as 9,900 nucleotide pairs) was used. Measurements were made using a Hewlett Packard digitiser interfaced with a 9820A calculator.

When polyoma DNA was incubated with gene 32 protein (Fig. 1*a*), only one denaturation region was seen per molecule of DNA (with one exception) and the size of the denaturation loop formed was about 5% (or 260 base pairs) of the full length of the molecule. The presence of gene 32 protein increased the length of the DNA molecule by about 4%.

When circular polyoma DNA molecules containing a

Table 1 Possible locations and frequencies of the individual denaturation sites induced by gene 32, measured on the two fragments produced by digestion of polyoma DNA using endonuclease *Hin*III

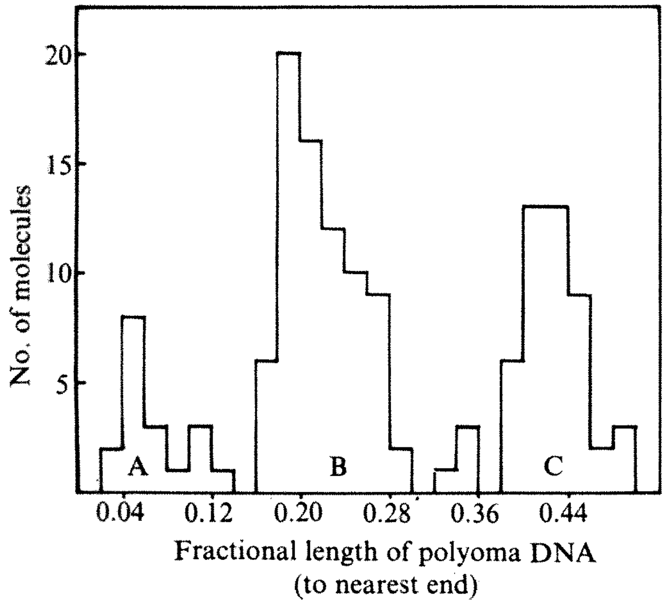
*Hin*III fragment, gene 32 protein complex	Possible locations	s.d.	Frequency
I	0.08* or 0.36	± .03	11%
II	0.20* or 0.24*	± .02	33%
III	0.03 or 0.47*	± .02	14%
IV	0.12 or 0.44*	± .02	27%
V	0.20* or 0.36	± .01	14%

Measurements on *Hin*III fragments were converted to percentage total genome, referred to the *Eco*RI cleavage site and mapped to the nearest end of a full length linear molecule. The two possible locations for each denaturation loop, depending on the orientation of the fragment, are shown with the most probable location asterisked. I and II correspond to 43% *Hin*III fragment species (Fig. 1); III, IV, and V correspond to 57% *Hin*III fragment species (Fig. 1).

denaturation loop were digested with restriction enzyme *Eco*RI (which cuts polyoma DNA at one unique site[7,9]) three types of molecule were observed, each with the denaturation loop at a particular site (Fig. 1A, B and C). Figure 2 shows that the three preferred sites for denaturation are located, respectively, at 0.07, 0.23 and 0.42 fractional length from the nearest end of the molecule and with frequencies of 12%, 52% and 36%. These observations are in agreement with those reported by Yaniv *et al.*[4].

The unambiguous location of these sites on the circular DNA molecule, however, could only be achieved using another specific restriction enzyme capable of distinguishing between the two ends of the linear molecule cleaved by *Eco*RI. This was accomplished using endonuclease *Hin*III which cuts polyoma DNA at two sites[7] generating two fragments, one 57±2% and the other 43±2% of the genome (Fig. 3). When polyoma DNA gene 32 protein complexes were digested using this enzyme, the two fragments were obtained, one about 43% of the genome with a denaturation loop at one of two sites, and the other about 57% of the genome with a denaturation loop at one of three sites (Fig. 1, I–V). Table 1 shows that four of the sites found on the *Hin*III fragments must be located in positions equidistant from the *Eco*RI site and thus together comprise two of the sites found on the *Eco*RI linears. As we knew the location of the two fragments on the circular map[7], we determined the absolute positions of the loops by comparing the *Hin*III data with the distribution of loops on the *Eco*RI linears.

Fig. 2 Location of denaturation sites (A, B, C) induced by gene 32 protein on *Eco*RI cleaved polyoma DNA gene 32 complexes (expressed as fractional length to the nearest end). Measurements were carried out to the midpoint of the denaturation loop. Average locations were: A, 0.07 ± 0.03; B, 0.23 ± 0.06; C, 0.42 ± 0.07. Relatives frequencies were: A, 12%; B, 52%; C, 36%.



Taking the 43% fragment first, each of the sites has two possible map locations, depending on which way the fragment is oriented (Fig. 4*b* and *c*). Because one of the loops is located at about the midpoint of the fragment either at 0.20 or 0.24 on the map, however, this immediately fixes the position of this denaturation region (II in Figs 1 and 4) as corresponding to B at 0.23 from the *Eco*RI linear map (also shown for comparison in Fig. 4). The other denaturation region observed on the 43% fragment could occupy either position 0.08 or 0.36 (Fig. 4*b*). Comparison with the *Eco*RI linear map shows that there is a denaturation region which could correspond to the 0.08 position but none at 0.36. This observation identifies site I (Figs 1 and 4) as being A on the *Eco*RI map. On comparing the frequencies of these sites (I and II) with the *Eco*RI frequencies, we found that whereas the frequency of denaturation site I on the small fragments agrees with that observed for site A on the *Eco*RI linears (11% as opposed to 12%) site II only accounts for 33% of the denaturation sites observed (as opposed to 52% incidence of denaturation site B on *Eco*RI). This would therefore imply that site B is a 'double' site, that is, one made up of two sites, equidistant from the *Eco*RI cleavage site. This interpretation would predict that another denaturation loop would be found on the 57% fragment, corresponding to map position about 0.77 (Fig. 3); site V fits these requirements (Fig. 4*g*). Its frequency of 14% brings the overall frequency of II+V to 47% in reasonable agreement with the 52% frequency observed for the B loop on the *Eco*RI linears. The alter-

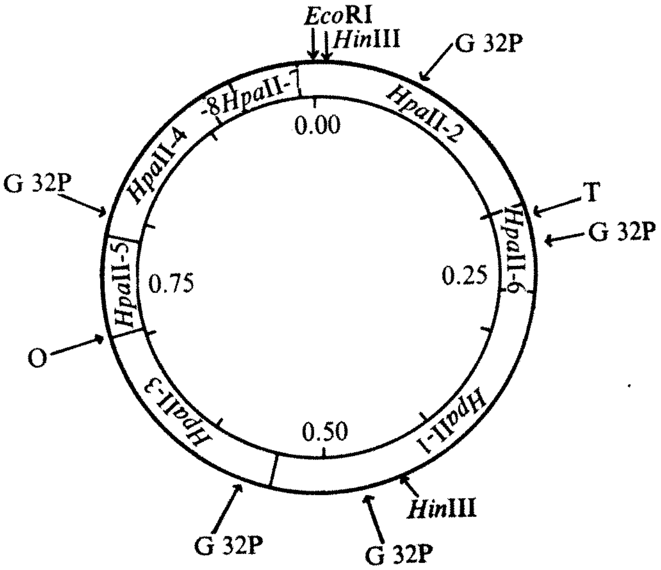


Fig. 3 Polyoma DNA map showing cleavage sites for enzymes *Eco*RI, *Hin*III and *Hpa*II (from Griffin *et al.*[7]), and gene 32 protein (G32P) denaturation regions referred to in the text. O and T are origin and termination of DNA synthesis respectively. Full length is 1 unit.

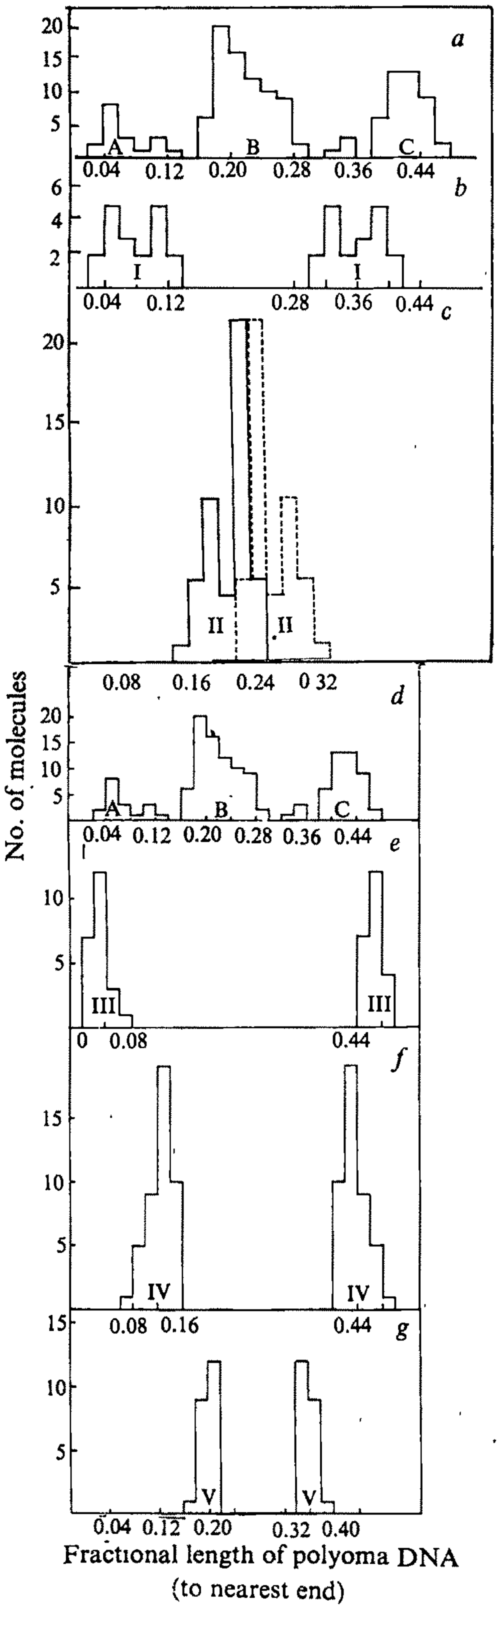
Table 2 Frequencies and locations of the various denaturation sites measured on *Hin* III fragments compared with distribution on *Eco*RI linears

*Eco*RI		*Hin*III	
Location	Frequency	Location	Frequency
0.07 ± .03	12%	0.08 ± .03	11%
0.23 ± .06	52%	0.23 ± .03	47%
0.42 ± .07	36%	0.44 ± .04	41%

Fig. 4 Alternative map locations of denaturation sites induced by gene 32 protein on the *Hin*III fragments expressed as the fractional genome length from the nearest *Eco*RI end. *a–c*, 43% *Hin*III fragment. *a*, Distribution of denaturation loops on *Eco*RIcleaved polyoma DNA–gene 32 protein complexes for comparison. *b*, *Hin*III 43% fragment with denaturation loop (I) shown in Fig. 1. *c*, *Hin*III 43% fragment with denaturation loop (II) shown in Fig. 1. *d–g*, 57% *Hin*III fragment. *d*, Distribution of denaturation loops on *Eco*RI linears as in (*a*) for comparison. *e*, *Hin*III 57% fragment carrying denaturation loop (III) as shown in Fig. 1. Note that the histogram on the right is not the 'mirror image' of the one on the left, as is the case in (*f*) and (*g*). This is a result of the second possible location extending to either side of the midpoint (0.5), and being expressed as fractional genome length from the nearest *Eco*RI end. *f*, *Hin*III 57% fragment carrying denaturation loop (IV) as shown in Fig. 1. *g*, *Hin*III 57% fragment carrying denaturation loop (V) as shown in Fig. 1.



native position for denaturation site V at 0.36 does not correspond to a site found on the *Eco*RI map.

For the two other denaturation sites observed on the large *Hin*III *fragment* (57%) the same approach was followed. Figure 4*e* and *f* shows that sites III and IV must occupy approximately equidistant positions in relation to the *Eco*RI cleavage site: one at map position 0.47 and the other at position 0.56 together accounting for site C at 0.43 on the *Eco*RI map (Fig. 4*d*). When the frequencies observed for these two locations are added a total of 41% is obtained in reasonable agreement with that observed for C (36%). Finally, data (not shown) from digestion of polyoma DNA gene 32 protein complexes with another enzyme—*Hpa*II—generating eight fragments[7], also confirms the presence of five easily denaturable regions.

In summary, there seems to be on polyoma DNA five sites which are readily denatured by gene 32 protein with map positions (Fig. 3) of approximately 0.08, 0.23, 0.47, 0.56 and 0.80 and frequencies of 11%, 33%, 14%, 27% and 14%, respectively. The *Hin*III data when expressed as percentage total genome and referred to the nearest end compares well with the *Eco*RI linear map (Table 2). Note that the preferred sites for denaturation by gene 32 protein correspond to *Hpa*II fragments 2, 6, 1, 3 and 4 (Fig. 3) and that 2 and 6 were the fragments found by Giffin *et al.*[7] as having the highest A+T/G+C ratio. The origin of DNA replication which has been mapped at 0.71 (refs 7 and 10) does not seem to be associated with an A+T-rich region whereas termination of DNA synthesis at 0.21 (Fig. 3) is closely associated with the most frequent denaturation site at 0.23. The present work using two different restriction enzymes overcomes the previous difficulties in trying to locate A+T-rich regions in circular viral DNA molecules[11,12]. The functional significance of each of the A+T-rich regions described in this study remains to be established.

We thank Dr M. Fried for laboratory facilities, for encouragement and for discussions; Dr L. V. Crawford (in whose laboratory the work was initiated) for help in preparing the manuscript; Dr B. Griffin for help with some experimental details; and Miss F. Crew for assistance. We acknowledge gifts of purified polyoma DNA from Dr M. Fried, of *Eco*RI from Dr R. Kamen and *Hin*III from Dr R. Roberts.

Note added in proof: Lescure and Yaniv (personal communication) also have evidence suggesting the presence of a gene 32 protein induced denaturation site mapping at ~0.80.

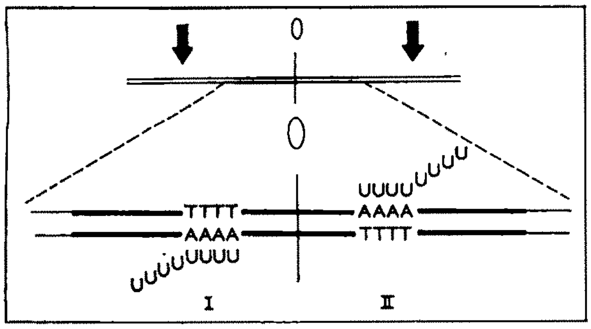
Proximity of deoxyadenylic-thymidylic acid clusters to origin of DNA replication in *E. coli* 15T$^-$ cells

CLUSTERS of deoxyadenylic-thymidylic (dA-T) and deoxycytidylic-deoxyguanylic acid (dC-dG) residues have been detected in DNAs from many sources[1,2]. The purine or pyrimidine clusters in denatured DNA can hybridise with complementary polyribonucleotides and the greater density of the complexes means that they can be separated from unreacted DNA by isopycnic centrifugation in CsCl or $\mathrm{Cs_2SO_4}$ (refs 1 and 2). These clusters are estimated to be 10–100 residues long and are distributed throughout DNA at intervals of 10^5–10^6 daltons (ref. 3). The dC-dG clusters have been implicated in the regulation of transcription in viruses[4–8], bacteria[1,9] and in nuclei (P. K. Bhattacharya and H.K., unpublished) from eukaryotic cells (for reviews see refs 3 and 10). Less is known about the function of clusters of dA–T residues which are as common in most DNAs[1]. Although in adenoviruses the presence of dA-T clusters has been correlated with the oncogenic potential[11] and Borst and Ruttenberg[12] found runs of dT on the transcribed strand of mitochondrial DNA, no further efforts have been made to associate regulatory or other functions with the presence of these clusters. We now report observations which suggest that clusters of dA-T may be involved in the initiation of DNA synthesis. The rationale for our investigation was that if such clusters were detected at or near the replication origin, it would be consistent with the proposition that they function in the initiation of DNA replication.

If a synchronised culture of *Escherichia coli* is pulsed with ^{3}H-thymidine when DNA replication resumes and subsequently chased with cold thymidine, newly replicated DNA near the origin is labelled whereas that farther from the origin and all of the unreplicated portion of the DNA is unlabelled (Fig. 1). Since replication in *E. coli* is bidirectional[13,14], labelled regions on both sides of the origin (0) would be anticipated (thick lines).

Fig. 1 Schematic representation of the experimental design. O, point of origin (starting point of DNA replication); I and II, two dA-T clusters of opposite polarity; the thick and the thin lines denote the labelled and unlabelled portions of cellular DNA, respectively; strings of Us, poly(U); the two arrows show the positions of breaks in DNA during shearing.



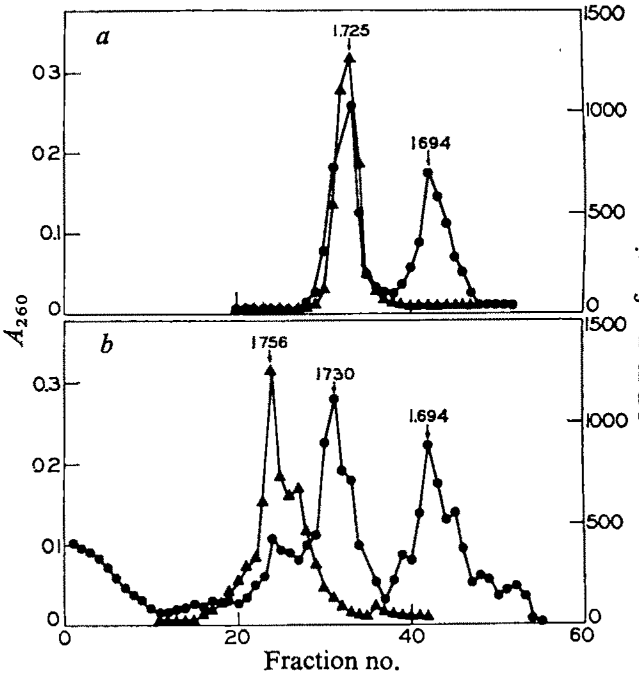


Fig. 2 Distribution in CsCl gradients of pulse labelled, sheared and denatured *E. coli* 15T$^-$ DNA (200 µg per sample) in the absence of any polyribonucleotide (*a*) and in the presence of 500 µg of poly(U) (*b*). DNA was extracted from synchronised, ^{3}H-thymidine-labelled cells, sheared, denatured and reacted with poly(U) as described in the text. The samples were centrifuged together with 120 µl of marker native *Cytophaga johnsonii* DNA (density in CsCl 1.694 g ml^{-1}, see ref. 1) in a Spinco SW 50.1 rotor, 38,000 r.p.m. at 8 °C. Fractions were collected at the end of the 48-h run. ●, Absorbance at 260 nm; ▲, radioactivity.

When this DNA is sheared into fragments shorter than the average distance between two adjacent clusters (breaks depicted by arrows in Fig. 1), denatured and reacted with a complementary ribopolymer, polyuridylic acid (poly(U)), fragments containing dA runs should band at the density higher than that of DNA alone (density of RNA is close to 1.9 g ml^{-1} in CsCl[14]). Fragments lacking dA runs should band at the normal density of denatured *E. coli* DNA (1.725 g ml^{-1} in CsCl[1,15]). (The unsheared DNA will band at the higher density since dA-T clusters are distributed evenly throughout *E. coli* DNA[1].) Thus, if a dA-T cluster (I in Fig. 1) is located between the two breaks, either inside or outside the labelled region, half of the labelled DNA (that strand which contains the dA run) should become heavier than the bulk of the unlabelled DNA in the presence of poly(U). If two dA-T clusters of opposite polarity (that is, with the dA segments present on opposite strands) are located close to 0, as are clusters I and II in Fig. 1, all the radioactive DNA will hybridise with poly(U) and become more dense than the bulk of the DNA, which is defined as the bulk of the ultraviolet-absorbing material. Thus, the experiment tells whether runs of dA are located close to the origin and whether they occur on one or both strands in that region.

Similarly, the occurrence of dC-dG clusters near the origin could be detected if polyriboguanylic acid (poly(G)) or the heteropolymer of guanylic and uridylic acids (poly(U,G)), is substituted for poly(U). Poly(U,G) has the same specificity as poly(G) but fewer technical problems are associated with its use[3,9,16].

A culture of *E. coli* 15T$^-$ (auxotrophic for thymine, arginine, methionine and tryptophan) was synchronised by the amino acid starvation technique[17]. The culture was supplemented with ^{3}H-thymidine (0.65 µCi, specific activity 1.56 Ci mmol^{-1}), immediately resupplied with the required amino acids and incubated for 15 s at 25 °C. Unlabelled thymidine was then added up to the concentration of 20 µg ml^{-1} and incubation continued for a further 2 min at 25 °C. The cells were chilled, collected and lysed by standard techniques. DNA was extracted[18] and divided into two portions, one of which was sheared by forcing the solution four times through a 27-gauge needle. Both DNA samples were then heat denatured[1] and each was divided further into three portions. Poly(U) was added to one portion and poly(U,G) to the second. The third contained no synthetic polynucleotide. A saturated solution of CsCl was added, the samples were centrifuged until equilibrium and the distributions of radioactive and ultraviolet-absorbing materials in the gradient were determined[3]. Some of the results are shown in Fig 2. Denatured DNA, not exposed to polyribonucleotide, banded in CsCl at a density close to 1.72 g ml^{-1} and the radioactive and ultraviolet-absorbing fractions practically overlapped (Fig. 2*a*). In the presence of poly(U) (Fig. 2*b*) the DNA came to equilibrium at a higher density and the ultraviolet-absorbing material was distributed over a wider range than in the control. All the radioactive DNA banded as a rather homogeneous peak well below the bulk of the DNA.

In several parallel experiments (not shown) the distribution patterns of the radioactive DNA and of the bulk of the unlabelled DNA in the gradient did not differ when: (1) the DNA was not sheared; (2) the pulse was longer than 15 s; (3) the pulse was begun more than 15 s after addition of the required amino acids; (4) either sheared or unsheared DNA was exposed to poly(U,G) instead of poly(U) and (5) DNA was obtained from non-synchronised cultures labelled as described.

The experiments summarised suggest that dA-T clusters (but not clusters of dC-dG) are located close to the replication origin in *E. coli* $15T^-$. Transposition by poly(U) of almost all the radioactive DNA from the density occupied by the bulk of cellular DNA suggests that at least two dA-T clusters of opposite polarity are located close to this point. The presence of a single heteropolymer composed of a run of dA residues followed by a run of Ts on the same strand, with complementary bases on the opposite strand, however, would account for the observed phenomena equally well.

We do not know how close these clusters are to the origin. They may be immediately adjacent to it, forming part of the sequence used by DNA polymerases to initiate DNA replication; or they may be as far as 500–700 nucleotide pairs away, half the length of the average DNA sheared in our conditions (unpublished observations). The latter estimate of this distance is probably too high in view of the relative homogeneity of the poly(U)-transposed radioactive peak (Fig. 2*b*). The fact that the dA-T clusters are also distributed throughout the DNA[1] may be related to repeated reinitiation of DNA synthesis[19].

The experiments described here do not suggest the precise role (if any) played by the dA-T clusters in DNA synthesis, although their location next to the starting point of replication may indicate some vital function. No information is available on the proximity of such clusters to the origin of DNA replication in other prokaryotic and eukaryotic cells. Identification of such structures in the vicinity of this site in DNA from other organisms would make a stronger case for their involvement in regulation of the replication process.

Variable redundancy in RNA transcripts isolated in S and G_2 phase of the cell cycle of *Physarum*

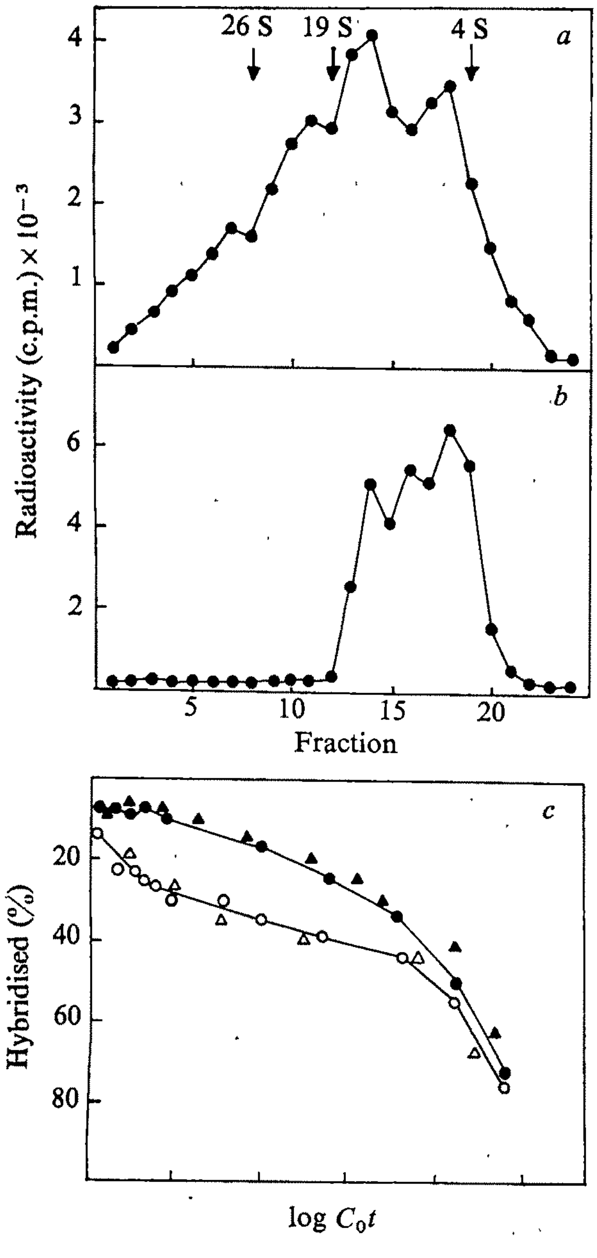
GENOMES of eukaryotes contain variable proportions of repeated base sequences of mostly unknown function[1]. It has been shown that nuclear RNA of sea urchin[2], rat[3] and *Dictyostelium*[4] also contains repetitive sequence elements, whereas polysomal messenger RNA (mRNA) does not. If mRNA is contained in the heterogeneous nuclear RNA, these sequence homology experiments suggest a selective processing of 3′-fractions of nuclear poly(A) RNA with unique base sequences. Most mRNA fractions and individual mRNAs so far studied[2,4-7] hybridise with single-copy DNA, with the exception of *Xenopus* embryo mRNA which contains both unique and moderately repeated sequences[8]. Functions for the repeated base sequences in RNA are not known and could involve regulation of transcription, processing, or translation, as well as copying of some sequences significant for DNA replication and recombination[1,9]. We have now used the naturally synchronous mitotic cycle of *Physarum*[10] to investigate whether there are changes in the degree of repeated sequences in RNA transcribed in S phase and G_2 phase.

We isolated poly(A)-rich RNA by affinity chromatography[11] from nuclei[12] and polysomes[13], and sedimented these molecules in sucrose gradients. The nuclear preparations were heterogeneous (Fig. 1*a*). They contained RNA fractions ranging from 4S to 30S, but no larger RNA molecules, whereas most of the poly(A)-rich RNA from polysomes sedimented with about 8S–15S (Fig. 1*b*). The RNA from nuclear preparations was then divided into RNA molecules of the size of polysomal RNA (Fig. 1*a*, fractions 13–22) and RNA molecules larger than polysomal RNA (Fig. 1*a*, fractions 1–12). Then the reassociation kinetics of these RNA molecules with DNA at an excess DNA concentration was determined[14]. We found that small molecules from nuclei and the RNA obtained from polysomes hybridised mainly with single-copy DNA (Fig. 1*c*) as judged from previous C_0t curves of nuclear DNA from *Physarum*[15]. A significant proportion of the heavy nuclear poly(A)-rich RNA had, however, hybridised at much lower C_0t values (Fig. 1*c*). To rule out hybridisation artefacts in comparing large and small RNA molecules, the heavy fraction of nuclear RNA was sonicated to about the size of polysomal RNA. The hybridisation kinetics of the shortened RNA molecules was indistinguishable from that of large RNA molecules (Fig. 1*c*).

From these observations we deduce that in *Physarum*, as in *Dictyostelium*[4], and perhaps in most higher cells[1], a fraction of nuclear RNA contains repeated base sequences which are lost in processing from the nucleus to the cytoplasm.

In the next experiment (and others not shown) we analysed the reassociation kinetics of nuclear poly(A)-rich RNA prepared in S phase or G_2 phase and found that the sample from G_2 phase contained a significantly higher proportion (35%) of redundant

Fig. 1 Sucrose gradient profiles and hybridisation kinetics of poly(A)-rich RNA from *Physarum polycephalum*. Plasmodia were grown[18] and labelled[11] as described previously, for 1 h with 100 μCi ml^{-1} ^{3}H-uridine. Nuclei[12] and polysomes[13] from *Physarum* were prepared using published methods. RNA was extracted with a phenol procedure adapted for *Physarum*[19–21], utilising trisisopropylnaphtalensulphonate for lysis and diethylpyrocarbonate as RNase inhibitor. Poly(A) RNA from nuclear and polysomal RNA was isolated by affinity chromatography on poly(dT) cellulose as reported previously[11,22] and fractionated on linear 5–20% sucrose gradients as published[11]. For hybridisation experiments aliquots of poly(A) RNA of about 10,000 c.p.m. were incubated with 1 mg ml^{-1} DNA in 2×SSC, 50 mM Tris, *p*H 7.2, 0.1% SDS in 50% formamide[3,14,23]. Nuclear DNA was prepared, purified, sheared and heat denatured as described previously[15]. At appropriate C_0t values the percentage of hybridisation was computed for each point from the radioactivity resistant to a mixture of RNase A and T1. At a C_0t value of 10^3 approximately 65–80% (700–900 c.p.m.) of the input RNA had hybridised. *a*, Profile of nuclear poly (A) RNA; *b*, profile of polysomal poly(A) RNA; *c*, hybridisation kinetics of poly(A) RNA from *Physarum*. ▲, Polysomal RNA; ○, large nuclear RNA molecules; △, large nuclear RNA, sonicated; ●, small nuclear RNA molecules.



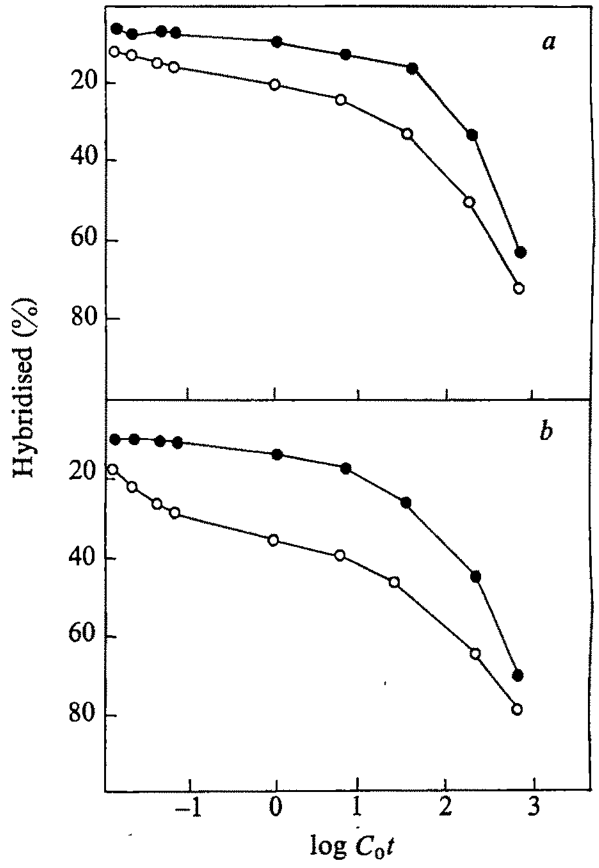


Fig. 2 Hybridisation kinetics of nuclear and polysomal poly(A) RNA prepared in S phase and G$_2$ phase. *Plasmodia* were labelled for 1 h in S phase (5–65 min post mitosis) and G$_2$ phase (4–5 h post mitosis). Preparation of subcellular poly(A) RNA fractions and hybridisation procedures were as described for Fig. 1. *a*, S phase of the cell cycle; ●, polysomal poly(A) RNA; ○, nuclear poly(A) RNA; *b*, G$_2$ phase of the cell cycle; ●, polysomal poly(A) RNA; ○, nuclear poly(A) RNA.

base sequences than that from S phase (20%) (Fig. 2). The hybridisation reaction of polysomal RNA prepared from S phase or G$_2$ phase was very similar (Fig. 2).

Differences in RNA synthesis in S phase and G$_2$ phase of *Physarum* have previously been claimed (for review see ref. 16) and we have since obtained some evidence for replication–transcription coupling[17]. The data presented in Fig. 2 suggest to us that replicating DNA may provide RNA polymerase B with other initiation sites for transcription than interphase chromatin, resulting in variable repetitive sequence elements in the nuclear RNA, possibly at the 5′-end of the original transcript. If one could generalise from this finding, we would predict that proliferating cells contain a lower degree of redundancy in their nuclear poly(A)-rich RNA than do resting cells.

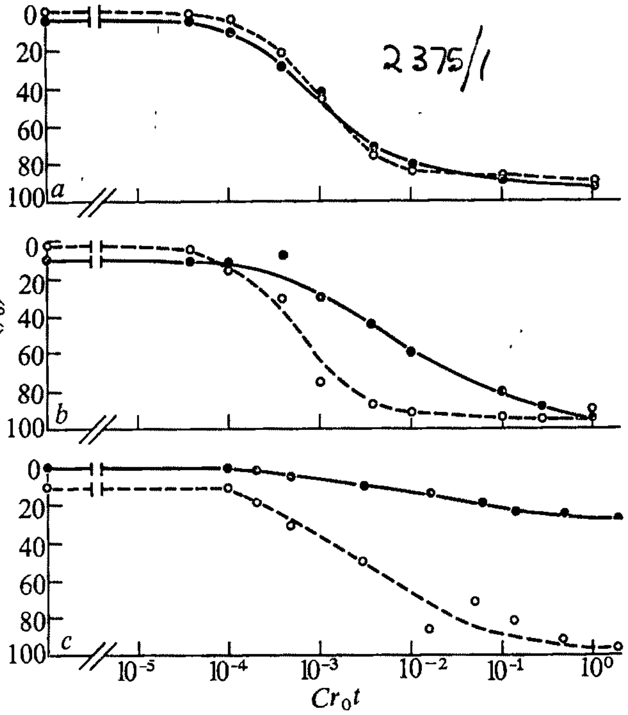
Deletion of α-globin genes in haemoglobin-H disease demonstrates multiple α-globin structural loci

FOUR clinical syndromes are associated with α thalassaemia: (1) the silent carrier state (α thalassaemia-2), with no clinical effect; (2) heterozygous α thalassaemia (α thalassaemia-1) in which a more severe defect in α-chain synthesis produces microcytic red cells, but little or no anaemia; (3) haemoglobin-H disease, usually the combination of α thalassaemia-1 and α thalassaemia-2, resulting in mild to moderate haemolytic anaemia, and (4) hydrops fetalis associated with haemoglobin Barts, an invariably fatal condition which represents the homozygous state of α thalassaemia-1 (for recent reviews see refs 1 and 2). To explain these syndromes, one hypothesis proposes that α thalassaemia-1 and α thalassaemia-2 are caused by a defect of greater and lesser severity affecting alleles of a single α-globin locus[3]. A second hypothesis is based on evidence that the α-globin structural gene is duplicated[4], the four syndromes may be the result of involvement of one, two, three or all four α structural genes by thalassaemia. In this study, we tested these hypotheses by measuring the number of α-globin structural genes in haemoglobin-H disease and the results firmly support the latter hypothesis.

Ottolenghi *et al.* and Taylor *et al.* showed that the defect in hydrops fetalis results from complete or partial deletions affecting all α-globin stuctural genes[5,6]. This implies that in α thalassaemia-1, half the normal number of α-globin genes are similarly affected. Since some normal α-globin chain is synthesised in haemoglobin-H disease, an intact α-structural gene must be present in the α thalassaemia-2 lesion If there is one locus for α-chain synthesis, patients with haemoglobin-H disease will also have half the normal number of α-structural genes, but if haemoglobin-H disease is the result of deletion affecting three of the four genes, patients will have a quarter the normal number.

α-Globin genes were measured in a Chinese patient with haemoglobin-H disease with complementary DNA (cDNA) enriched in α-globin sequences. The specificities of this probe and the cDNA enriched in β-globin sequences are shown in Fig. 1. The α and β cDNAs annealed at the same rate and to the same extent to the haemoglobin-A mRNA, but the α cDNA annealed at about one-tenth the rate of the β probe to haemoglobin-H mRNA which contained $\alpha:\beta$ sequences at a ratio of 1 : 9. Less than a quarter of the α cDNA annealed to RNA from hydrops reticulocytes, whereas the β cDNA annealed completely. Thus, as much as 25% of the α cDNA used in these experiments could represent contamination with β-globin sequences.



2375/1

Fig. 1 Annealing of human globin cDNA to globin mRNA. The α cDNA was prepared as described previously[6]. Globin mRNA was isolated from the postribosomal supernatant lysate[7] of reticulocyte-rich blood of a patient with autoimmune haemolytic anaemia. (This preparation of mRNA directed the synthesis of three times more α chain than β chain in the Krebs ascites cell-free system[3].) The mRNA was transcribed into cDNA in a 75-µl reaction mixture which contained 300 U ml^{-1} avian myeloblastosis virus polymerase, 20 µg ml^{-1} RNA template, 5 µg ml^{-1} oligo(dT) (PL Biochemicals), 100 µg ml^{-1} actinomycin (Calbiochem), 50 mM Tris (*p*H 8.3), 6 mM MgCl$_2$, 10 mM dithiothreitol (Calbiochem), 0.5 mM each of TTP, dCTP, dATP and 0.1 mM ^{32}P-dGTP (New England Nuclear Corp., specific activity 110 Ci mmol^{-1}); and incubated at 37 °C for 30 min. The cDNA was isolated and incubated in the presence of excess template RNA. That cDNA which annealed was isolated on hydroxylapatite and recovered as described[6]. It was then annealed to haemoglobin-H mRNA (α:β ratio = 1:9 on translation in Krebs ascites cell-free system), until 88% of the cDNA was annealed. The single stranded material was eluted from hydroxyl apatite and used as the probe for α sequences. The β cDNA was prepared by transcription from the haemoglobin-H mRNA, with ^{3}H-α GTP (Schwartz-Mann, specific activity 10 mCi mmol^{-1}) as the radioactive label, and was used as a probe for β sequences without further enrichment The purity of the α and β cDNA was tested by annealing to (*a*) Hb-A mRNA, (α: β = 1:1), (*b*) Hb-H mRNA and (*c*) to hydrops reticulocyte RNA. The conditions of annealing were similar to those described[6] except that 200 c.p.m. each of ^{32}P-α probe and ^{3}H-β probe were present together in each reacting mixture. ●, α cDNA; and ○, β cDNA. For (*c*) it was assumed that 1% of the total RNA was mRNA.

The contamination and the possible partial annealing of the α cDNA with the gene for ζ-globin chain[5] may complicate the measurement of α-globin genes. We attempted to circumvent these problems by measuring the rate of annealing of the cDNA to reconstituted mixtures of normal and hydrops cellular DNA. The rate of annealing of the α cDNA to a mixture containing equal parts of each should be similar to that found if half the normal number of α-globin genes are present. The rate of annealing to a mixture containing 1 part of normal to 3 parts of hydrops DNA would represent a quarter of the normal number of α-globin genes. These rates were compared with the rate of annealing of the α cDNA to cellular DNA from a patient with haemoglobin-H disease (Fig. 2). The α cDNA annealed to the haemoglobin-H DNA at a rate identical to the mixture which contained 25% non-thalassaemic cDNA and 75% hydrops DNA. In contrast, the cDNA specific for β-globin genes annealed to all the cellular DNAs and their mixtures at about the same rate.

We conclude that a patient with haemoglobin-H disease has a quarter the normal number of intact α-globin structural genes. This provides direct evidence that a non-thalassaemic person must have at least four α-globin genes per diploid cell. These data do not rule out the possibility that some multiple of four α-globin genes per cell is present. The fact that α-structural abnormalities constitute at least 25% of the total haemoglobin in the heterozygous state[9], however, makes the higher numbers unlikely.

On the basis of studies of α-globin structural mutants, it has been suggested that the number of α-globin structural genes varies in different populations. The finding of two α-chain mutants, haemoglobins Buda and Pest each comprising about 25%, together with 50% normal haemoglobin-A in the same person in a Hungarian family, firmly supports the two-locus theory[10]. On the other hand, the fact that haemoglobin-A is absent in Melanesian homozygous for haemoglobin J-Tongariki[11,12] and in some Oriental patients with the combination of haemoglobin Q and α thalassaemia-1 (ref. 13), suggests that only one locus is present. The method described here can be used to quantitate α-globin structural genes in these different syndromes.

We thank Professor J. M. Bishop for helpful comments.

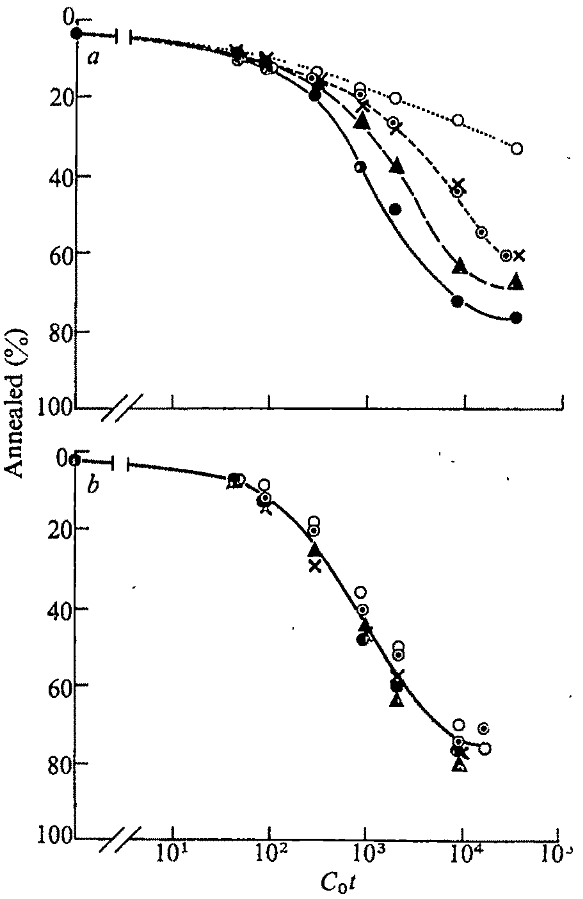


Fig. 2 Annealing of human globin cDNA to cellular DNA. DNA was isolated from the livers of an infant with hydrops and a non-thalassaemic infant, and from the spleen of a Chinese patient with haemoglobin-H disease by methods previously described[6]. The latter patient has a microcytic anaemia with haemoglobin of 10 g, reticulocyte count 4.6%, Hb A_2 0.9%, HbF 0.5%, Hb H 15% and no Hb Constant Spring. One sibling studied has heterozygous α-thalassaemia. 200 c.p.m. each of ^{32}P-α cDNA (*a*) and ^{3}H-β cDNA (*b*) were annealed to cellular DNAs in the following conditions: 5.8 mg ml^{-1} cell DNA, 0.5 M NaCl, 2 mM EDTA, 40 mM Tris (*p*H 7.4) at 68 °C, total volume 260 µl, for 10 min to 120 h. Annealing was assayed with hydroxylapatite. ●, Non-thalassaemic DNA; ○, hydrops DNA; ▲, mixture of equal parts of non-thalassaemic and hydrops DNA; ⊙, mixture of 1 part of non-thalassaemic to 3 parts of hydrops DNA; ×, haemoglobin-H DNA.

Stereochemical basis of heat stability in bacterial ferredoxins and in haemoglobin A2

MOST enzymes are quickly inactivated above about 55 °C, but those from thermophile bacteria are stable for long periods at higher temperatures[1]. We do not know why, because so far their structures have proved too complex. For example, although the tertiary and quaternary structures of the enzyme glyceraldehyde phosphate dehydrogenase from lobster muscle and from *Bacterium stearothermophilus* are alike, their amino acid sequences differ by more than 130 out of some 330 positions, which makes it hard to decide why the stearothermophilus enzyme is more stable. The electron transfer protein ferredoxin offers a better chance, because its single polypeptide chain contains fewer than 60 residues; its structure is known, and its heat stability and amino acid sequence have been determined in both mesophile and thermophile bacteria. We have built an atomic model of this protein, replaced its amino acid side chains in turn to correspond to the published sequences and searched for possible causes of the greater heat stability of ferredoxins from thermophile bacteria. We found that it arises mainly from external salt bridges linking residues near the amino terminus to others near the carboxy terminus. Haemoglobin A_2, a minor fraction of adult human haemoglobin which is a little more heat stable than the major fraction, haemoglobin A, seemed another good choice because its amino acid sequence differs from that of A at only 10 positions. The atomic model suggests that at only two of these positions are the replacements likely to contribute to the extra stability of haemoglobin A_2, one replacement providing an extra hydrogen bond between the α_1 and β_1 subunits and the other adding two non-polar interactions to a surface crevice within the β subunits To account for the increased heat stability of the two proteins, the extra bond energy

provided by these interactions need not be larger than 10 kJ for ferredoxin or 5 kJ for haemoglobin A_2.

The three-dimensional structure of ferredoxin from the mesophile *Micrococcus aerogenes* has been determined[2] (Fig. 1). It has two active complexes spaced 12 Å apart, each consisting of four atoms of iron and four of inorganic sulphur joined in a distorted cube. The iron atoms of one complex are linked to Cys 8, 11, 14 and 45 and those of the other to Cys 18, 35, 38 and 41. The molecule contains tyrosines in positions 2 and 28, each having one face in contact with one of the Fe_4S_4 complexes and one edge with water.

The thermal stabilities of ferredoxins from two mesophile clostridia (*Clostridium pasteurianum* and *C. acid urici*) and from two thermophile species (*C. tartarivorum* and *C. thermosaccharolyticum*) have been reported[3]. The amino acid sequences of these four ferredoxins are closely related to the sequence of *M.aerogenes* (Table 1). For instance, the sequences of *M. aerogenes* and *C. thermosaccharolyticum* show thirty identities, including the pattern of the eight cysteines which are linked to the eight iron atoms. There are ten conservative replacements (for example Ala→Ser; Ser→Thr; Thr→Val; Val→Ile; Gln→Glu) and in eight of these the side chains are external; the two internal replacements are Tyr 2→His at one of the active sites, and Ile→32 Val; both these can be accommodated without change of tertiary structure. There are 12 non-conservative replacements in 11 of which the side chains are external; the one internal replacement Pro 52→Val can be accommodated without change of tertiary structure. Compared to the sequence of *M. aerogenes* the sequences of the four *Clostridium* ferredoxins contain two insertions, one between positions 21 and 22 and the other between 26 and 27, and one deletion at the C-terminus. Fig. 1 shows that the insertions occur at the corners of an external loop and that the C-terminus is also external, so that these modifications can also be accommodated without changing the tertiary structure which seems to be determined primarily by the pattern of cysteines linked to the Fe_4S_4 complexes.

The enzyme from *C. pasteurianum* is completely inactivated after 2 h at 70 °C, that from *C. acidi urici* retains 20% of its activity, that from *C.tartarivorum* half, and that from *C thermosaccharolyticum* 90% (ref 3). To explain these differences we have assumed that the polypeptide chains of all four clostridia maintain a tertiary structure closely similar to that of *M. aerogenes*, we have built an atomic model of the latter and have altered the pattern of side chains in turn to correspond to the four different sequences of *Clostridium*. We have found some of the amino acid replacements such as Thr 5→Asn or Thr 49→Val to be clearly neutral, although others seem highly significant.

For instance, the nature of the aromatic residues in positions 2 and 30, next to the two Fe_4S_4 complexes, varies in different species (Table 2). Ferredoxin from *C. pasteurianum*, which is the least heat stable, has Tyr at 2 and Phe at 30. In *C. acidi urici*, which is more stable, Phe 30 is replaced by Tyr; its OH can form a hydrogen bond with the OH of Ser 10. In *C. tartarivorum* and *C. thermosaccharolyticum* Tyr continues to occupy position 30, but Tyr 2, which seems to make no hydrogen bond, is replaced by His which can make a hydrogen bond to the sulphur lone pair electrons of Cys 43. Tanaka *et al.* drew attention to some of the most interesting characterisics of the thermophile enzymes

53	Asn	Val	Val	Ser	Lys	Lys

The salt bridge from Asp 6 to Lys 29 may not be sterically favourable and is therefore shown as a broken line. The numbering of the residues is as in Table 1; to relate it to Fig. 1, subtract 1 from numbers 23–26 and 2 from all numbers above 27. Ferredoxin from *P. elsdenii* is reported to be heat labile[13] but no quantitative data for its heat stability are available. On the basis of its salt bridges as shown here it should be intermediate between *C. acidi urici* and *C. tartarivorum*.

when they pointed out that glutamine or glutamic acid in positions 31 and 44 can be hydrogen bonded to other amino acid side chains. In fact, glutamates 7 and 25, glutamate or aspartate 6, and aspartate 39 can also form such bonds. Aspartate 39 forms a salt bridge with the α amino group which seems to be invariant. Two of the salt bridges specific to the thermophile enzymes (24–25 and 29–31) are between neighbours or next nearest neighbours in straight segments of the chain and would not necessarily have to break when the chain unfolds, but two others are placed in the most effective positions possible by clamping residues near the amino terminus to residues near the carboxyl terminus (His 2–Gln or Glu 44 and Glu 7–Lys 53). The sequence of the less stable ferredoxin from *C. tartarivorum* differs from that of the more stable one from *C. thermosaccharolyticum* by replacements in only two positions. Glutamines 31 and 44 are replaced by glutamates. His 2 and Lys 29, which are common to the ferredoxins of both clostridia, can form hydrogen bonds with either the uncharged carbonyls of the glutamines or the charged carboxyls of the glutamates; the latter, being salt bridges, are stronger and must therefore account for the extra stability of the ferredoxin from *C. thermosaccharolyticum*. If these conclusions are correct, then the differences between the heat stabilities of the different ferredoxins should diminish on weakening the salt bridges, for example with increasing *p*H which would discharge histidine 2, or with increasing ionic strength.

In addition to these polar interactions one might have expected the thermophile enzymes to show extra non-polar interactions, but comparison of the sequences does not point to any position where the thermophile enzymes contain a residue providing consistently more non-polar contacts than any of the amino acid side chains occupying the same position in the mesophile enzymes.

We now turn to human haemoglobin, a protein consisting of four subunits joined in a tetrahedral array. At 45° oxyhaemoglobin A_2 is denatured six times more slowly than A (ref 4). The two proteins differ in only ten positions in the β chains (known as δ in haemoglobin A_2) (Table 3). Seven of these are external, two lie in surface crevices and one lies in the $\alpha_1\beta_1$ contact. Analysis of the external replacements shows that their effect, if any, should be to stabilise haemoglobin A rather than A_2. One replacement (126) in a surface crevice provides an additional non-polar contact between helices A and H within the same β chain of haemoglobin A_2. The replacement in the $\alpha_1\beta_1$ contact (116), introduces one extra hydrogen bond between the guanidinium group of Arg G18(116)β_1 and the carbonyl oxygen of Pro GH2(114)α_1 of haemoglobin A_2 (for illustration of the $\alpha_1\beta_1$ contact see refs 5 and 6.) Dissociation at the $\alpha_1\beta_1$ contact seems to determine the degree of resistance to alkaline denaturation of haemoglobin[6]. The amino acid differences between haemoglobins A and A_2 suggest that the extra hydrogen bond between residues 114α_1 and 116δ_2 is decisive in making A_2 more resistant to heat denaturation. If this is correct, then haemoglobin Lepore Boston, a δ–β hybrid in which the N-terminal six residues are δ and the rest β, should have a susceptibility to heat denaturation

Table 3 Interactions in human haemoglobin A and A_2

Residue no.		A β	A_2δ	Position	Structural role
Probable gains in A_2					
116	G18	His	Arg	$\alpha_1\beta_1$ contact	Arg forms H-bond to CO of Pro GH2α
126	H4	Val	Met	Surface crevice	Additional non-polar contact with Val A11(14)β
Probable losses in A_2					
12	A9	Thr	Asn	Surface crevice	Thr OH may bond to CO of Lys A5β
22	B4	Glu	Ala	External	Glu may form weak salt bridge to His G19β
50	D1	Thr	Ser	External	Possible loss of non-polar contact with CH_3 of Ala D4
117	G19	His	Asn	External	See 22
Probable neutral replacements					
9	A6	Ser	Thr	External	None
86	F2	Ala	Ser	External	Probably none
87	F3	Thr	Gln	External	None
124 or 125	H2 or H3	Pro	Gln	External	None

similar to that of haemoglobin A, and deoxyhaemoglobin, in which the subunits are joined by salt bridges, should be more heat-resistant than oxy, CO or cyanomethaemoglobin.

In conclusion, thermophile ferredoxins are stabilised by extra salt bridges between external polar groups and by additional hydrogen bonds but not, apparently, by more non-polar contacts. The heat stability of haemoglobin A_2 compared to A is accounted for by one extra hydrogen bond at the contact between the α_1 and δ_1 subunits and possibly two non-polar interactions within the δ subunits.

The denaturation data of ferredoxin refer to irreversible loss of activity accompanied by loss of the iron sulphur clusters from the protein; this requires at least two kinetic steps, unfolding of the chain and dissociation of the cluster, which cannot be separated. Even so the order of magnitude of the extra stabilisation energy provided by the salt bridges and hydrogen bonds can be estimated from the difference in the observed rates of denaturation. The data of Devanathan *et al.*[3] suggest that the half times for denaturation ($t_{1/2}$) in the four proteins differ approximately in the order of 1 : 5 : 10 : 20. The corresponding differences in free energy of activation, $\Delta G = RT2.3\ \log\Delta t_{1/2}$ amount to 4.6, 6.6 and 8.5 kJ mol^{-1} at 70 °C for each protein relative to the slowest, assuming G (ground state) to be the same for each protein. This suggests that the total extra free energy of stabilisation provided by the additional bonds in the thermophile ferredoxins is rather less than 10 kJ mol^{-1}. The rate of denaturation at 45 °C of haemoglobin A exceeds that of A_2 about sixfold, which corresponds to an extra stabilisation energy of 5 kJ mol^{-1}. These energies are surprisingly small. Similar conclusions were reached for the difference between the free energy of activation needed to denature triose phosphate isomerase from rabbit muscle and *B.stearothermophilus* (R. C. Fahey and J. I. Harris, unpublished). It seems that in monomeric enzymes the extra energy of stabilisation can be provided without disturbance of the tertiary structure by a few extra salt bridges on the molecular surface; in oligomeric enzymes by some extra salt bridges, hydrogen bonds or non-polar bonds at the subunit interfaces.

We thank Drs Lyle Jensen, L. C. Sieker and E. T. Adman for allowing us to use their unpublished coordinates of ferredoxin and for checking our conclusions; and Drs J. Kinderlehrer, M. Levitt and A. Warshel for discussion.

Isolation of newly synthesised myosin filaments from skeletal muscle homogenates and myofibrils

LARGE and rapid changes in the concentrations of myofibrillar protein can occur during hypertrophy and atrophy of skeletal and cardiac muscle[1,2]. Understanding of the regulation of these changes will require analysis of the steps between the initiation of transcription and the degradation of the protein to amino acids. The role of post-translational steps in these processes has generally been ignored since there has been no way to isolate biochemically intermediates of myofibrillar assembly. This is unfortunate since the physiological and metabolic regulation of such steps may control the rate of incorporation of new protein into this organelle, and thus the levels of functional contractile protein in the cell. Present understanding of myofibrillar assembly has come mainly from ultrastructural studies. In embryonic[3], regenerating[4] and rapidly growing muscles from young animals[5], electron microscopy suggests that polymerised thick and thin filaments can aggregate to form myofibrils *de novo* and/or insert into pre-existing myofibrils. In contrast, microscopy of normal adult muscle usually does not reveal these structural aspects of myofibrillogenesis, although isotope studies showed that contractile proteins are constantly synthesised and degraded in the muscle cell[1,2,6], even in the absence of net growth. This may be because only a small fraction of protein exists as nascent filaments not yet integrated into fibrillar sarcomeres, and/or because these assembly steps may be too rapid to be captured by electron microscopy. We report here the isolation of a population of thick and thin myofilaments that may constitute such an intermediate in myofibrillar assembly.

Female Sprague–Dawley rats (200–220 g) were killed and the muscles excised, minced and soaked in an EGTA-pyrophosphate containing relaxing solution, and then homogenised in a solution containing EGTA. The homogenate was centrifuged at 800*g* to sediment myofibrils and centrifugation was repeated until the supernatant was devoid of myofibrils. Electron microscopy of this fraction revealed the presence of numerous free thick and thin filaments which tended to form 'bundles' through lateral and longitudinal aggregation. By supplementing the post-myofibrillar supernatant with 2 mM ATP, the aggregation of these myofilaments could be prevented, in turn making clearer visualisation of these filaments possible by negative staining and the subsequent centrifugation of this fraction at 10,000*g* for 10 min to remove additional subcellular material from this fraction. Finally, these filaments were purified further by treatment with 1% Triton X-100 based on previous reports that no myofibrillar components are extracted with this non-ionic detergent[7]. Figure 1 illustrates a field of such filaments after this purification. The amount of protein in this preparation, measured by the Lowry method[8], varied with the degree of homogenisation of the muscle but was between 10% and 15% of total myofibrillar protein when homogenisation was carried out for 30 s at 14,000 r.p.m. in an MSE blade type homogeniser.

Since the release of filaments in the whole muscle homogenate is likely to depend in part on endogenous muscle ATP necessary for actin-myosin relaxation[9], we quantified the amount of myofibrillar protein found in the purified filaments as a function of the time that minced muscle was soaked before homogenisation. When this step lasted 3 h, with repeated replacement of the washing solution, virtually no protein was detected in this preparation and no free filaments or aggregated filaments were found in the crude muscle homogenate examined with the electron microscope. Thus, the free and/or loosely held filaments are probably trapped on the surface of the myofibrils through, in part, rigour-links caused by washing out of endogenous ATP from the mince. This suggested an alternative method for isolating fresh homogenate filaments, based on their entrapment on myofibrils and subsequent release. Myofibrils were, therefore, prepared from this 'rigour homogenate' and gently treated with Mg-ATP relaxing solution, resulting in the release of approximately 10–15% of myofibrillar protein in the form of thick and thin filaments. When myofibrils were viewed with the phase contrast or electron microscope during treatment with Mg-ATP relaxing solution, they seemed at first to stiffen, followed by a swelling and fanning out of filaments at the periphery of the fibrils, suggesting the release of filaments from the fibrillar periphery. In related studies, we have shown that the whole homogenate filaments and filaments released from fibrils lack M-line protein(s) of 190,000 and 170,000 daltons and Z-line protein(s) of 90,000 daltons, and have decreased amounts of protein larger than 200,000 daltons (ref. 7 and J. D. E., unpublished).

To investigate the significance of the easily releasable filaments, the rats were first injected with tritiated leucine into the tail vein after a 24 h fast. After times ranging from 5 min to 24 h, the animals were killed and the isolated filaments were prepared from the whole homogenate directly or through entrapment on the myofibrils and subsequent filament release. The residual undispersed myofibrils were also prepared in each case. The preparations were electrophoresed on 5% SDS-acrylamide gels and the stained myosin heavy chain band was sliced and hydrolysed (Fig. 2). Tritium was counted in one portion of the hydrolysate and the remainder was assayed for leucine (Table 1).

The specific activity of the myosin heavy chain in the filament fractions was substantially and reproducibly higher than that obtained from residual myofibrils (Table 1). Furthermore, the differences in these specific activities seemed to decrease with time after isotope injection. The precise time dependence of this difference must, however, be regarded as tentative because small variations in filament yield may affect the exact difference obtained in a given experiment. We have also obtained similar results in the heart (J. Sims and R. Z., unpublished). The quantitation of this phenomenon and its applicability to other myosin and myofibrillar components is being studied.

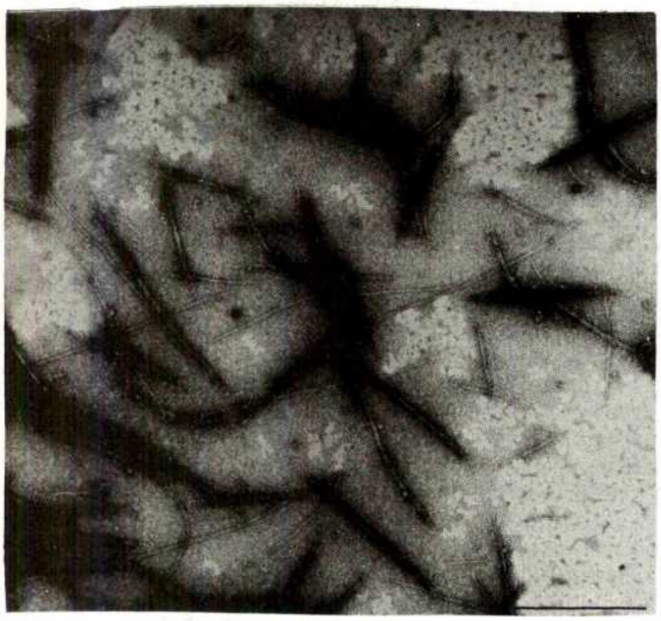

Fig. 1 Electron micrograph of thick and thin filaments isolated from the post-myofibrillar supernatant fraction of a fresh muscle homogenate. Mixed rat back muscle was excised and coarsely minced in 0.1 M KCl, 2 mM $MgCl_2$, 2 mM EGTA, 2 mM $Na_4P_2O_7$, 1 mM dithiothreitol (DTT), 0.01 M Tris-maleate, *p*H 6.8 at 0 °C. The muscle was then disrupted with an MSE homogeniser for 30 s at 14,000 r.p.m. in 10 volumes of a solution of the same composition without pyrophosphate, followed by 5–10 strokes in a glass Dounce homogeniser. The homogenate was filtered through two layers of cheesecloth and centrifuged at 800*g* for 10 min. This supernatant was centrifuged again at 800*g* for 10 min and then adjusted to a final ATP concentration of 2 mM to prevent aggregation of myofilaments. The ATP-supplemented filament preparation was then centrifuged at 10,000*g* for 10 min. The post-10,000*g* supernatant was then supplemented with Triton X-100 to yield a final concentration of 1%, and placed on ice for 5 min. Next $CaCl_2$ was added to a final concentration of 2 mM and, after 15 min, the aggregated filaments were pelleted by centrifugation at 15,000*g* for 1 h. These filaments were then redispersed in 0.1 M KCl, 2 mM $MgCl_2$, 2 mM EGTA, 2 mM ATP, 1 mM DTT, 0.01 Tris-maleate, *p*H 6.8 (Mg-ATP relaxing solution) and negatively stained with aqueous 2% uranyl acetate. The calibration bar equals 0.5 μm.

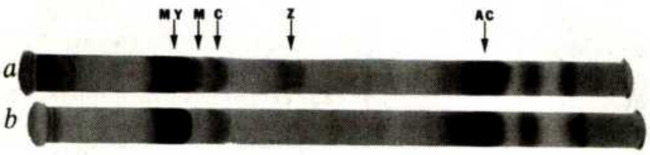

Fig. 2 SDS gel electrophoresis of filaments and residual myofibrils isolated from a fresh muscle homogenate. Isolated filaments were prepared as described in Fig. 1 and the 800*g* pellet obtained from the muscle homogenate was used to obtain myofibrils. The myofibrils were prepared by washing the pellet six times with 0.1 M KCl, 2 mM $MgCl_2$, 2 mM EGTA, 1 mM DTT, 0.01 M Tris-maleate, *p*H 6.8, once with the same solution containing 1% Triton X-100, and twice without Triton. Each preparation was then electrophoresed on 5% SDS-acrylamide gels as described previously[12]. Similar patterns are obtained when filaments are released from fibrils although the proportions of myosin and actin varied between preparations. A, residual myofibrils; B, thick and thin filaments; MY, myosin heavy chain; M, M-line protein(s); Z, Z-line protein(s); C, C-protein; AC, actin. Assignment of protein bands is according to ref. 7.

In most protocols for the isolation of contractile proteins, the 'insoluble' myofibrillar fraction serves as the starting point for extraction and purification. Discarding the supernatant fraction which we have found to contain myosin filaments of substantially higher specific activity could seriously affect estimates of protein synthetic rates and protein half lives based on these rates. In the whole animal system used here, apparent rates of synthesis would seem lower than the actual rates, particularly at the earlier time points[10].

The myofilaments found in the supernatant fraction must be either filaments which are not as tightly incorporated into

Table 1 Standard specific radioactivity of the myosin heavy chain in filament fractions and in residual myofibrils

Experiment	Time after injection	Filaments (standard specific activity)	Residual myofibrils (standard specific activity)
1	5 min	2,648	767
2	5 min	3,620	695
3	5 min	1,453	586
4	30 min	2,263	852
5	3 h	2,873	1,513
6	24 h	2,885	2,027

Rats were injected with 300–2,000 μC; of ^{3}H-leucine. In experiments 1 and 2, filaments and myofibrils were isolated directly from the fresh whole muscle homogenate as described in Fig. 1, Fig. 2 and in the text. In experiments 3 to 6, filaments were released from 'rigour homogenate' myofibrils. Filaments were released from the myofibrils by 10 passages through a Pasteur pipette of the fibrils in Mg-ATP relaxing solution (Fig. 1). The filaments were separated from undispersed fibrils by centrifugation at 800*g* for 10 min after which the supernatant was recentrifuged at 800*g* for 10 min. The filaments in the 800*g* supernatant were pelleted by centrifugation at 100,000*g* for 3 h. The myosin heavy chain band (MY) was sliced from the stained gels (Fig. 2). A 3 mm slice containing 20–50 μg protein was hydrolysed in 5 ml of 6 N HCl–0.1% mercaptoethanol at 110 °C for 24 h. The samples were then placed at 0 °C for about 12 h and then centrifuged at 500*g*. The supernatant was evaporated to dryness and the precipitate was washed three times with H_2O by evaporation. Samples were resuspended with 1.3 ml of H_2O and then 1 ml was counted in 10 ml of Scintisol with a Packard liquid scintillation counter. 0.2 ml was used to assay for leucine according to the isotope dilution method of Rubin and Goldstein[13]. Results are expressed as standard specific activity, = d.p.m. μmol^{-1} leucine × rat weight (g) per μCi injected.

the fibrils or filaments which actually exist in a cytoplasmic pool before their attachment to fibrils. (Since the amount of myofibrillar protein recovered in the supernatant fraction at least partly depends on the extent of tissue disruption, a portion of these filaments must be released from myofibrils.) Further experiments do not support the hypothesis that the high specific activity filaments arise from the preferential release of filaments from the myofibrils of red compared with white fibres (our work in preparation).

Morkin's electron microscopic autoradiographic studies of postnatal skeletal muscle suggested that newly synthesised myofilaments are added to the periphery of pre-existing fibrils[11]. It is likely that we have, at least in part, obtained a preferential separation of these newly synthesised peripheral filaments from the less dissociable 'core' myofibrils. In non-growing heart muscle or skeletal muscle undergoing little or no increase in length, peripheral addition would seem to be a reasonable way to add new myofilaments. In hypertrophying heart muscle or in skeletal muscles from prenatal or young animals, which are rapidly lengthening along the fibre axis, addition of new filaments to the ends of myofibrils[5,14] may also be important.

A similar law may govern water freezing in minerals and living organisms

THERE is an interesting similarity between the freezing of water in minerals and in biological tissues. Mazur[1,2] observed that many living organisms lose viability at threshold temperatures near −10 °C. After investigating this phenomenon from the point of view of possible mechanisms by which living cells suffer damage on freezing, he concluded that a key step in the freezing process is the penetration of ice into the cell to nucleate the internal water, and that at −10 °C ice can penetrate the membrane, whereas above this temperature, it cannot. This implies that the water in the cell-membrane pores or a portion of them, starts to freeze at about −10 °C. From the Kelvin equation which describes freezing in terms of the ice–water surface tension and the radius of cylindrical capillaries, Mazur deduced that[1] "the lower melting point of ice in a capillary can account for the barrier properties of the plasma membrane". He observed, however, that "there is a large quantitative discrepancy. The evidence suggests that the plasma membrane ceases to be a barrier at approximately −10 °C. On the basis of equation (4), (ref. 1) the critical pore radius at −10 °C is 30 Å, whereas the estimated pore size from permeability studies is 3–8 Å". To account for the discrepancy he postulated that the contact angle of water in the membrane pores is not 0 ° but 80 °. This enabled him to find the simple relationship

$$\Delta T \approx 52/a \tag{1}$$

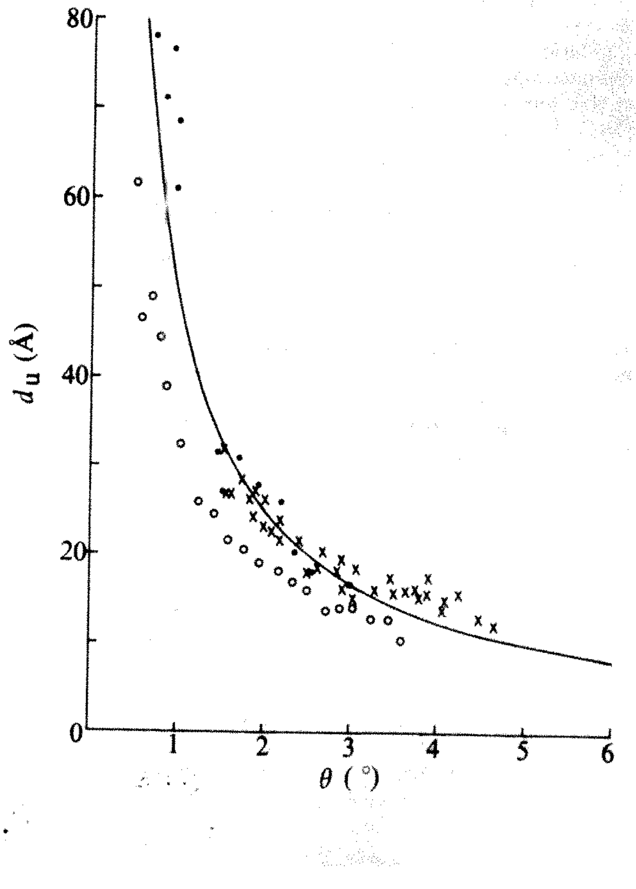
where ΔT is the freezing point depression and a is the pore radius in Å, which predicts that water in 5 Å pores will freeze at −10 °C and thus agrees with experimental observations on membrane pore sizes.

This result is strikingly similar to an equation that we have found governs the thickness of the unfrozen water layer, d_u, on mineral surfaces:

$$d_u \approx 50\ (1/\theta) \text{ or, rearranged, } \theta \approx 50/d_u \tag{2}$$

where d_u is in Å and θ is temperature in degrees below 0 °C; d_u is calculated from experimental results and is equal to the ratio of the volume of unfrozen water V, to the specific surface area of the solids S. For non-porous adsorbents or for porous systems in the unsaturated state, that is, when their pores are not completely filled with the adsorptive (a substance capable of being adsorbed but which is not in the adsorbed state) or adsorbate, d_u is considered to be the statistical average thickness of the layer of unfrozen water. In saturated porous systems the ratio V/S is equal to the hydraulic radius, r_h of the pores. For cylindrical capillaries, often used as convenient but probably not

Fig. 1 Measured relationships between the average statistical thickness of the layer of unfrozen water (d_u) and temperature below 0 °C (θ) for three different mineral materials. Also included is the smoothed theoretical curve fitted to the results (continuous line, $d_u = 50\,\theta^{-1}$). ×, Kaolinite; ●, basalt; ○, limonite–goethite.



very realistic models of pores, $r_h = r/2$ where r is the capillary radius. For slit-type capillaries, $r_h = d$ where d is half the distance of separation between the plates; slit-type capillaries are a reasonable model for pores between plate-shaped minerals such as the alumino-silicates. The value of the coefficient in equation (2) was derived from measurements[3] of the unfrozen water content as a function of temperature on several partially frozen, water-saturated, mineral–water mixtures, each differing quite considerably in their crystallographic structure and physicochemical properties. These data for powdered basalt (a primary, basic rock), limonite–goethite (iron oxide) and kaolinite (an aluminosilicate mineral) are depicted in Fig. 1. The fitted curve is simply a plot of equation (2). We discuss elsewhere how deviations from this freezing law may arise in porous bodies as a result of differences in distribution of pore size, and how these may affect the calculated thickness of unfrozen water layers at temperatures near 0 °C. At lower temperatures, however, (−6 to −10 °C) when the thickness of the unfrozen water layer lies in the range of 5–8 Å, water–ice phase composition data for most mineral materials fall on the same temperature–thickness curve. Note that the similarity between these three different materials would not have been as apparent if instead of layer thickness, unfrozen water content was plotted as a function of θ using the more common units of g H_2O/g solid, because of differences in specific surface areas between the various materials.

We will further analyse the possible physicochemical basis for the freezing process. Our hypothesis may be elaborated as follows: In the force field caused by the forces emanating from the solid or resulting from surface curvature of the liquid in capillary pores, the chemical potential or the vapour pressure of the water is lowered compared with that of bulk pure water. The smaller the capillary and the thinner the layer of adsorbed water, the lower the water chemical potential. When freezing is initiated at 0 °C, only the water that has chemical potential equal to free water solidifies whereas water in narrow pores, or affected by the solid surface and therefore having lower potential, remains unfrozen. As the temperature of the system is lowered further, the chemical potential of water, in the form of ice, is correspondingly decreased[4] creating a gradient that successively induces increments of the unfrozen water to solidify. Thus, two condensed phases of water can coexist at temperatures below 0 °C—that is, unfrozen liquid water and ice crystals. The unfrozen water can be present either in narrow capillaries or as thin adsorbed layers. At each temperature the chemical potential of the unfrozen water is equal to that of ice at this temperature, being in thermodynamic equilibrium and physical juxtaposition with the ice. The relationship of thickness of unfrozen water to temperature can therefore be viewed as dependent on (and also a measure of) the change in chemical potential of water with the radius of pores or the distance from the solid surface.

The mode of change in chemical potential of a capillary condensate with pore size is well established; the Kelvin equation is a special case applicable to cylindrical capillaries. In general, the chemical potential depends on the nature of the liquid (its molar volume and surface tension) and is independent of the nature of the solid composing the walls of the pores. For cylindrical and slit-type capillaries it is proportional to r_h^{-1}. For thin adsorbed layers it was shown for nitrogen[6,7] and for water[8], that adsorption data relating some measure of the chemical potential (vapour pressure) to the thickness of adsorbed layer for many solid adsorbents fall on a common curve termed by de-Boer and his associates[6], the standard t curve. Thus the t curve seems to be characteristic of the adsorbate or adsorptive but virtually independent of the adsorbent. From these standard t curves it is also found that the chemical potential of the adsorbate usually varies with d^{-3} as expected for the classical van der Waals interaction resulting purely from dispersion forces acting between an atom and a slab[9]. Accordingly, and in view of the previous discussion on the mode of near-surface water freezing, we suggest that many porous bodies and adsorbents may have a common freezing curve relating the layer thickness of unfrozen water or the hydraulic radius of pores containing them, to temperatures below 0 °C. Our data show that this is the case for a variety of minerals (Fig. 1). From the data of Mazur it seems also to be the case for biological systems.

One puzzling and unresolved finding is that the coefficient in equations (1) and (2) relating the temperature below freezing point to the hydraulic radius or the equilibrium thickness of water on the surface (or when converted to other units,relating the chemical potential to the distance from the surface) is smaller by a factor of five to ten than that predicted from the Kelvin equation. The tentative explanation of Mazur[1] that the contact angle of the water in the pores is not 0 ° but 80 ° does not seem to be sufficient in view of the fact that three different adsorbents are involved in deriving the relationship given in equation (2). Also, the fact that even at every close proximity to the solid the interaction still seems to vary with d^{-1} rather than with d^{-3}, is puzzling. Thus none of the presently known modes of interaction between solid porous adsorbent and liquid adsorbate seems to account completely and quantitatively for these experimentally determined generalised freezing relationships.

Corrigenda

In the article "Evidence that mitogenic lectins induce changes in membrane fluidity" by R. E. Barnett, R. E. Scott, L. T. Furcht and J. H. Kersey (*Nature*, **249**, 465; 1974) the authors request that the following changes be made to the method. "The organisation of the membrane lipids was probed with a mixture of 3 spin labels, methyl 6-(4′,4′-dimethyloxazolidinyl-N-oxyl)-heptadecanoate (10%), N-(1,1-dimethyl-2-hydroxethyl)-6-(4′,4′-dimethyloxazolidinyl-N-oxyl)heptadecamide (30%), and 1-[2-(1,1-dimethyl-2-hydroxethylimino)cyclopentyl]-1-(4′,4′-dimethyloxazolidinyl-N-oxyl)undecane (60%). The observed differences in the order parameter could also be caused by differential uptake or metabolism of the labels by the cells."

In the article "Role of f-gravity in cosmological models" by C. Sivaram, K. P. Sinha and E. A. Lord (*Nature*, **249**, 640; 1974) equation (2) should have read

$$\dot{R}^2 = (\tfrac{8}{3})\pi G\rho R^2 + (\tfrac{2}{3})\Lambda c^2 R^2$$

The Λ-term occurs with a *positive* sign, so that a minimum in the function $R(t)$ will occur only if the coupling constant G_f is *negative* (and Λ_f positive). Thus the conclusions of this paper are valid only if the coupling constant of strong gravity is taken to be negative. The authors wish to thank J. V. Narlikar for pointing this anomaly out to them.

reviews

Is all that is not verse just prose?

P. N. Johnson-Laird

The Psychology of Language: An Introduction to Psycholinguistics and Generative Grammar. By J. A. Fodor, T. G. Bever and M. F. Garrett. (Mc-Graw-Hill Series in Psychology.) Pp. xvii+537. (McGraw-Hill: New York and London, 1974.) £8.80.

MOLIERE'S hero, Monsieur Jourdain, was amazed to learn that he had been speaking prose for 40 years. Is it really true that he spoke not just prose, but deep structures and transformations? Knowledge is a fine thing, indeed; but the question prompts another more serious one. How could it be shown that transformational grammars are wrong in principle?

One approach would be to establish the existence of certain sentences that they could not properly characterise. But grammatical transformations are an exceedingly powerful computational device, and it is very doubtful whether there are any such sentences. Another approach would be to show that no formal device could specify what sequences of words are grammatical and what sequences are ungrammatical. But even if this thesis were to be proved, which is extremely unlikely, it would establish too much. It would show that language was not governed by any determinate set of rules. Perhaps the general idea of transformational grammar is empirically invulnerable, and it remains only to establish the best grammar within its confines—a view which seems to be held by its current practitioners. There is, however, one aspect of the general theory that may be potentially testable. Transformational grammar should provide the basis for a psychology of language. It is this thesis, initially advanced by Chomsky, that Fodor, Bever and Garrett have set out to explore. Their original disciplines were, respectively, philosophy, linguistics, and psychology; and as one might expect from so talented an interdisciplinary team they have produced a comprehensive and thoughtful book.

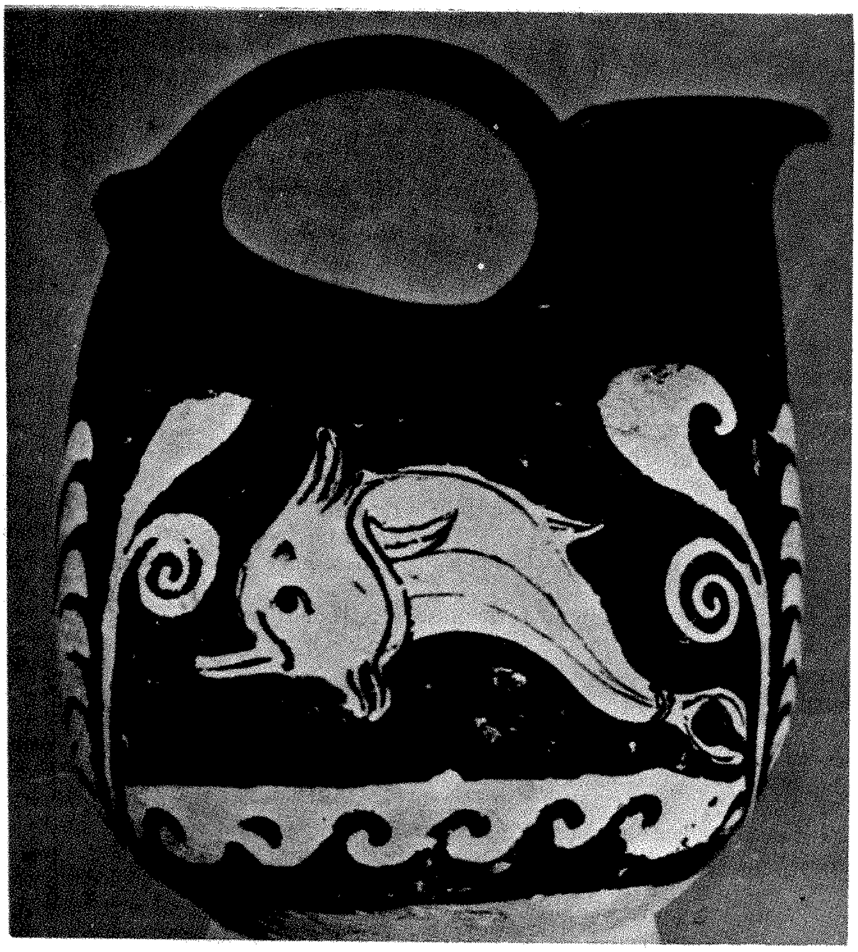
It is not difficult to appreciate why transformational grammar has proved so popular with psycholinguists. The authors review the deficiencies of its linguistic predecessors, the taxonomic grammars of the structuralist tradition, and show how neatly these grammars matched the outdated psychological assumptions of neobehaviourism. As Chomsky was one of the first theorists to point out the linguistic deficiencies of taxonomic grammars, it is scarcely surprising that his alternative approach to language was so appealing. His key assumption was that each sentence is derived by a series of transformations from an underlying deep structure specifying its fundamental grammatical relations. Later, of course, he came to believe that there is an interpretative component that also operates on the deep structure of a sentence in order to yield its essential meaning. So the crucial empirical test is whether it is possible to find traces of such structures and processes in a person's production and understanding of sentences. After one early inspirational article in *Psychology Today* (the American version), Chomsky was quick to close this empirical loophole. He invoked his notorious distinction between a speaker's knowledge or linguistic competence and how he exercises this knowledge in actual linguistic performance. The grammar is intended to apply only to linguistic competence—an assumption that has proved baffling to the point of apoplexy for those psychologists working within the Empiricist tradition.

A theory of linguistic performance might, however, incorporate a theory of competence couched in the form of a transformational grammar. Fodor, Bever and Garrett review the psycholinguistic literature in order to evaluate this proposition. They consider in detail studies of the production, perception and memory of sentences, naturally concentrating on the work that they and their colleagues have carried out at MIT. The moral they draw from their review is simple, but equivocal. There is evidence for the psychological reality of the notion of deep structure; there is little evidence for the psychological reality of processes corresponding to grammatical transformations. The authors draw a similar moral from their survey of studies of language acquisition. There is little evidence that children actually acquire grammatical transformations; there is, however, evidence that the order in which they master different sorts of sentence depends upon how difficult it is to relate them to their corresponding deep structures.

What an extraordinary state of affairs. It is as though each act of a play ended with a tableau appropriate, say, to *King Lear* although it had no discernable plot (or else it turned out to be that of *Charley's Aunt*). This is a problem that the playwright can resolve only by such time-honoured devices as, "with one bound the hero was free". Unfortunately, Fodor, Bever and Garrett have been unable to untie their hero; but there is perhaps an alternative explanation of the psychological phenomena. Indeed, looking closely at the text, one discovers such a possibility, which the authors have in their hands but let slip. They write (p. 270): " . . . so long as the deep structure is assumed to be that syntactic representation of a sentence which is semantically interpreted, hypotheses about the psychological effects of deep structure features tend to be confounded with hypotheses about the psychological effects of semantic relations". This confounding factor is the crux of the matter. One of the authors' typical experiments establishes that when a click is presented in the middle of a sentence, its apparent location migrates towards a boundary between clauses. The migration occurs even if there is no explicit boundary in the surface structure of the sentence. The authors accordingly argue that deep structure clauses have a perceptual integrity that leads to the relocation of events which interrupt them. Yet the crucial factor could be, not the coherence of a clauses's underlying syntactic relationships, but the coherence of its meaning. Transformational grammar is, however, by no means the only grammatical theory to assume that clauses have a meaning: proponents of Halliday's systemic grammar, for example, may be equally heartened by the conclusion that the semantic denouement is more important that the syntactic staging.

The main weakness of the book is the result of the authors' reluctance to look over the fence into their neighbour's backyard. They do not consider any of the current alternatives to transformational grammar and, in particular, the approach to language developed by the artificial intelligentsia working with computers. One suspects that they made a deliberate editorial decision to exclude this work—a great pity because many of the issues that they fail to resolve look more than susceptible to a procedural approach. In most other respects, however, the book is successful. Again and again, one is impressed by the authors' ability to think beyond an 'obvious' approach to a topic. They take a discerning route through the literature; and it is a real intellectual pleasure to follow in their footsteps.

The book is sophisticated but accessible. It is the definitive defence of the relevance of Chomsky's work to psycholinguistics, unlikely to be surpassed in its scope or thoroughness. Yet the defence fails. At the one point at which the general theory of transformational grammar is empirically vulnerable, it is all too vulnerable. The book probably marks the end of an era. It is unlikely that anyone will ever again mount so comprehensive a defence of transformational psycholinguistics. Monsieur Jourdain may go back to speaking simple prose. □



A Greek dolphin ceramic from the fourth century BC. From *Dolphins (The Undersea Discoveries of Jacques-Yves Cousteau)*. By Jacques-Yves Cousteau and Philippe Diolé. Translated by J. F. Bernard. Pp. 304+105 colour photographs. (Cassell: London, May 22, 1975.) £5.00.

Slipper animalcule

Paramecium : A Current Survey. Edited by W. J. Van Wagtendonk. Pp. xviii+499. (Elsevier Scientific: Amsterdam, London and New York, 1974.) $53.90.

THE genus *Paramecium* is familiar to most biologists and to many other scientists because it occupies a place in most courses on elementary biology. The amount of attention that has been paid to it in biological research is reflected in the fact that it has been the subject of more than 4,000 scientific papers and 4 monographs, the most recent of which is this volume edited by Professor Van Wagtendonk.

The book contains eight chapters contributed by workers actively engaged in research using *Paramecium*, and is said to provide "an up-to-date evaluation of research on all aspects of *Paramecium* biology." The eight subjects covered are: morphology, taxonomy and general biology; mating types; surface antigens; behaviour and motor responses; growth patterns and morphogenesis; structure; nutrition; and intracellular particles. Most chapters refer to the literature published up until 1969 or early 1970, though all are provided with addenda in which reference is made to work of the following two or three years. There is also a comprehensive bibliography of publications on *Paramecium* since 1953, the date of an earlier monograph on the subject by Wichterman.

The general introductory chapter by Vivier will be found the most useful by the average reader because it can be understood without much previous knowledge of the organism. This is not generally true of the other chapters, several of which assume an extensive background knowledge about the organism and specific facets of its biology, to which one is not introduced elsewhere in this book; most readers will not find such chapters fully comprehensible without preliminary reading of earlier work. All of the authors have, however, given an interesting account of the new knowledge being discovered at the frontiers of research upon *Paramecium* and all of the chapters contain much useful information for the protozoologist and cell biologist engaged in research and teaching, which recommends this volume as a valuable work of reference.

The reader will not find here any extensive information on nuclear function, on general physiological activities such as ionic regulation, contractile vacuole function or respiration, or on a number of minor facets of research on *Paramecium*, so that the monograph is not a comprehensive work. In a chapter on nutrition one might expect to find an account of the types of food eaten and the manner of entry into the body; not just a very detailed survey of the chemical dietary requirements for the growth of the animal. The view that mating types correspond to sexual types (p. 68) is less satisfying than the view that every *Paramecium* is hermaphrodite, producing gametic nuclei of both sexes, with mating types acting as devices to encourage cross fertilisation, analogous to self sterility and similar mechanisms that ensure cross pollination in plants. In the magnificently illustrated chapter on structure, a conventional analytical approach would have more successfully presented the information than the attempted synthetic method by which the authors built up a view of the structure from the component molecules, macromolecules and organelles.

The book is illustrated with a large number of electron micrographs and many other figures of a uniformly high standard. Errors and omissions in the figures, legends and tables are few, but are irritating and probably could have been avoided, although there are commendably few spelling errors.

Michael A. Sleigh

Astrophysical standards

Astrophysical Formulae: A Compendium for the Physicist and Astrophysicist. By Kenneth R. Lang. xxvii+735. (Springer: Berlin and New York, 1974.) $78.80.

In view of the enormous range of topics at present covered by astrophysics, it might be thought that a book which "is meant to be a reference source for the fundamental formulae of astrophysics" from nucleosynthesis to astrometry, would automatically be doomed to failure; but Kenneth Lang's attempt succeeds to a remarkable extent. The subject is divided into seven topics, grouped into five chapters—continuum radiation; monochromatic radiation; gas processes; nuclear astrophysics and high energy particles; astrometry and cosmology—and each topic is developed from first principles. This treatment, and the inclusion of several figures and tables of physical data, may make the book useful to the non-astronomical physicist, as promised in the subtitle, although beyond the basic development of each section the bias becomes increasingly too astrophysical for general use.

The disadvantage of this approach is that the discussion of any particular type of astronomical object becomes scattered throughout the text: neutron stars thus occur in such contexts as 'cosmology' (collapse of massive body), 'nuclear astrophysics' (URCA process), 'gas processes' (equation of state) and 'high energy particles' (X-radiation accretion in binary systems); similarly, the table of pulsar properties appears within the chapter on continuum radiation where the formula for dispersion measure is derived. (The pages of this table, incidentally, are printed in the wrong order.)

The comprehensive, 47 page, index minimises this drawback, and also allows quick access to the 69 tables of physical and astronomical data, the latter ranging from the planetary satellites through globular clusters to radio galaxies and quasars. A listing of the tables and figures in the contents section would have been useful though none is given. There are the inevitable misprints, for example "NGC 1270" for 1275 on page 554, and "log M_v" instead of M_v in the stellar luminosity function (Fig. 43); and there are also some omissions: Saturn X is missing from the list of satellites and the eccentricity and inclination of Pluto's orbit are not given in Table 57.

By its very nature a book of this kind cannot include enough information for day-to-day research, and its price too is likely to make it appear predominantly on library shelves. There is no doubt, however, that it will be an important reference work for any astrophysicist requiring basic information in a field outside his own, not just because of the concise presentation and clear explanation of the results, but also because it presents nearly 2,000 references, which include original sources from as far back as 125 BC (Hipparchus). This book should for many years remain one of the standard reference works in astrophysics.

Nigel Henbest

Slime organisms

The Mycetozoans. By Lindsay S. Olive. Pp. x+293. (Academic: New York and London, January 1975.) $23.50; £11.30.

The slime molds, both cellular and acellular have become increasingly popular over the last few years. Yet I suspect that most experimental biologists have little appreciation of the wealth of forms that exist and of how many riches are waiting to be tapped. In this book, Lindsay Olive does two things. He gives an admirable summary of some of the experimental studies of *Dictyostelium* and *Physarum* and, more important, discusses all the lesser known forms that are related in various interesting ways.

This is a monograph of the Mycetozoa in the classical sense. It discusses the taxonomy, the phylogeny, the morphology (including modern electron microscopic cellular morphology), and, in many cases, the experimental biology of all the known slime molds. What is most extraordinary is that many of the unusual organisms, some of which become 'missing links' between major groups, have all been described by Lindsay Olive himself. One would have thought that all the main types of organisms had been discovered long ago, but in the tradition of Roland Thaxter, Lindsay Olive, often in collaboration with Carmen Stoianovitch, has described many new species and whole new groups of organisms that were quite unknown until a few years ago. Because of the radical nature of these forms, Olive has not followed the well worn position of the past that myxomycetes and cellular slime molds be considered fungi. The main reason for this tradition was that the organisms were discovered by mycologists. Even though Olive himself is a mycologist he has taken the global view that the slime organisms are more closely allied to the protozoa and has fearlessly called them all Mycetozoa. This fine book, therefore, has much to offer to the protozoologist, the mycologist, the cell biologist, and the developmentalist.

Calcium and secretion

Calcium and the Secretory Process. By Ronald P. Rubin. Pp. xiii+189. (Plenum: New York and London, 1974.) $18.00.

The central importance of calcium in a number of secretory processes—especially those in which secretion occurs by exocytosis—is now well established and Dr Rubin has provided us with a useful survey of the present position.

His book is divided into an introduction and three main chapters. In the first he reviews in considerable detail evidence for a role of calcium in a variety of secretory systems. The information presented in this chapter is excellent but suffers somewhat from a lack of balance in approach. The classical model system for the study of calcium in neurosecretion, the neuromuscular junction, is discussed only cursorily whereas many pages are devoted to discussions of whether calcium participates in the secretion of, for instance, the thyroid and other glands. In spite of the existence of many good reviews on the more classical system, I am quite sure that before being subjected to a steeplechase of secretory phenomena the reader would have benefited from a clear explanation of the role of calcium in secretion from the neuromuscular junction. This would have led naturally to a full discussion of other neurosecretory systems including the adrenal medulla and neurohypophysis and would have provided a sound base for examining systems in which the role of calcium is less clear.

The section entitled 'The role of calcium in secretion' provides a critical survey of current hypotheses. Restricting himself more or less to the classical secretory systems Rubin discusses the various mechanisms that may underlie cadcium-dependent exocytosis. The reader cannot fail to be struck by the absence of good experimental evidence on the ultimate mechanism by which calcium effects exocytosis and it is a pity that Dr Rubin does not point more clearly to hopeful new lines of attack.

In the final chapter Rubin discusses the involvement of cyclic AMP in secretion. Although no clear answer emerges, this chapter will be useful to those interested in this vexed question.

Parts of this book are of undoubted interest and will be useful to students of secretion; but the volume as a whole is rather unsatisfactory and its treatment of secretion is neither complete enough nor rigorous enough to ensure that it will not date rapidly.

P. F. Baker

obituary

Max Gluckman, Nuffield Research Professor of Social Anthropology in the University of Manchester, died in Jerusalem on April 13 during the tenureship of a visiting professorship at the Hebrew University. He was 64.

Born in Johannesburg, Gluckman began a brilliant academic career at the University of Witwatersrand and went to Exeter College, Oxford in 1934. After being engaged in fieldwork in Zululand from 1936–38, he joined the staff of the Rhodes–Livingstone Institute of Northern Rhodesia. There he embarked on field research in Barotseland, later to form the basis of his researches in anthropological jurisprudence. As director of the Institute from 1941–47, he laid the foundations of what was eventually to become the Manchester School of Theory and Research in Social Anthropology. He expanded the Institute's publication department to reach both a lay and an academic readership, organising contributions from a wide range of central African social and anthropological problems. He accepted a lectureship at Oxford in 1947, but moved in 1949 to the University of Manchester, where the chair of social anthropology had been specially created for him. He was primarily interested in establishing a research school and began by making his department homebase for his Rhodes–Livingstone team. The main aims of his research workers was to investigate the stresses and strains of modernisation, as well as the tribal custom and law. By the late 1950s the department had extended its research interests to India and the Middle East. He planned extensive and still continuing programmes of collaboration in research and teaching with the Israeli universities, among whose first projects were field studies by Israeli students in Beduin communities. With his confidence and drive, he organised and dominated the celebrated Gluckman seminar. His circle of contacts and the respect conferred on him by foreign visitors were invaluable links with other fields and views, and his researches led to the publication of *The Judicial Process among the Barotse of Northern Rhodesia,* an analysis of the concept of the 'reasonable man' in African jurisprudence. As chairman of the Association of Social Anthropologists, he organised in 1963 the first Anglo–American conference on new trends in the discipline. Among many academic honours were election as a fellow of the British Academy in 1969, and as an honorary member of the American Academy of Sciences in 1970. Gluckman was a very controversial man and will be remembered for the thought and discussion which he will continue to provoke.

announcements

Award

The **Johann–Georg–Zimmerman Prize** has been awarded to **Peter Magee** for his accomplishments in cancer research.

Appointments

J. W. Murray has been appointed Professor of Geology and head of the department in the University of Exeter.

The title of Central Electricity Generating Board Professor of Corrosion Science has been conferred on **P. R. Swann.**

International meetings

June 5, **Yeasts in industry,** Birmingham (Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1X 8PS, UK).

June 16–18, **Protein and membrane structure and function,** Honolulu (C. S. McLaughlin, Department of Molecular Biology and Biochemistry, University of California at Irvine, Irvine, California 92664).

July 14–18, **Origins and achievements of the Greenwich Observatory 1675–1975,** London (The Secretary, The Organising Committee, 4th Joint IAU/IUHPS Symposium, National Maritime Museum, Greenwich, London SE10 9NF, UK).

July 20–26, **Continuous culture,** Oxford (The Conference Secretariat, Society of Chemical Industry, 14 Belgrave Square, London SW1X 8PS, UK).

Miscellaneous

Moon mission. NASA is asking for proposals for flight experiments from prospective investigators interested in participating in the Lunar Polar Orbiter mission (June, 1980). The latter is capable of extending to the entire moon, orbital and surface science results obtained from previous lunar missions (especially Apollo), and may serve as a prototype for similar ones to Mars and Mercury. Further information (by June 15, 1975) from: Dr F. D. Martin, Program Manager, Advanced Programs and Technology, Lunar Programs Office, Code SM, NASA, Washington, DC 20546.

Person to Person

Oceanography supervisor. Employed graduate working in London wishing to study for a higher degree in the history of oceanography seeks University Supervisor (Anita McConnell, 11 Arbor Court, Lordship Road, London N16, UK).

Accommodation wanted. British professor, on sabbatical leave from Canada, seeks furnished accommodation somewhere in the UK for his family (10, 7, 4) for the academic year 1975–76. 4 bedrooms, plus study, good-sized garden and easy access to open country essential (Dr A. R. Pugh, Department of Romance Languages, University of New Brunswick, Fredericton, New Brunswick, Canada).

There will be no charge for this service. Send items (not more than 60 words) to Robert Vickers at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

nature *May 22, 1975*

No time to be squabbling

A ROUTINE day at the United Nations in New York? No, a session at the Congress of the World Meteorological Organisation, one of the UN's specialised agencies, held recently in Geneva. At the end of the debate, South Africa was suspended from WMO until it renounces its policy of racial discrimination. The voting was 66 in favour, 25 against and 14 abstentions. In the same session the congress voted 81–14 to invite to WMO meetings observers from National Liberation Movements recognised by the Organisation of African Unity or the League of Arab States. Thus do some international scientific organisations conduct themselves these days; already the Food and Agricultural Organisation, UNESCO and the World Health Organisation have taken comparable restrictive measures against South Africa, and the recent Israel affair still causes a good deal of embarrassment at UNESCO.

> **Mr Tsou-Ching-meng** (China) deplored the regime imposed by white racialists in South Africa. His delegation considered that the proposal to suspend South Africa from Membership was right and proper. He stressed the sympathy of the Chinese people towards those struggling against colonialism and racialism in South Africa.
>
> **Mr Degefu** (Ethiopia) expressed his delegation's condemnation of the South African policy against non-white Africans as well as of that country's occupation of Namibia. Despite repeated condemnations, South Africa had not renounced its policy of racial discrimination.
>
> **Mr Pojani** (Albania) announced his full support of the proposal to suspend the Membership of South Africa. He deplored the aid given by imperialistic powers which enabled the South African regimes to continue.
>
> **Mr Fonseca** (Portugal) stressed that the democratic country he represented had nothing in common with the Portugal of 1974, which had been a colonial and fascist one. His Government severely condemned all forms of oppression, discrimination and inhuman treatment. He regretted that none of the documents made any mention of the new Portugal.

The very existence of South Africa is, of course, an affront to a majority of nations—indeed many of those who voted to retain South Africa in membership spoke of their abhorrence of her racial policies. And the depth of feeling can never be fully appreciated by the unoppressed whites of Europe. Nonetheless these latter also have deep feelings about the nature of science and the need for its pursuit to be free from politicisation, especially of the amateurish and self-congratulatory type. It is to the credit of the International Council of Scientific Unions (ICSU) that it has thus far been able to stand clear of most of the political nonsenses—although this has been at the expense of China's membership, since she resolutely refuses, despite all invitations, to be alongside Taiwan in the same meetings. It is also to the credit of the UNESCO staff that what gets to the conference table in that assembly has so far generally been universally acceptable.

But the question is bound to be asked—is the international science scene becoming increasingly politicised these days?

Was it ever otherwise, retort some of the wiser folk in the business—it's just that these days the west can be outvoted every time, so the politics are not those favourable to western countries; remember how the west used to vote to exclude China. This is a sane historical point of view, and history teaches us why people's present attitudes are what they are. Historical perspective, however, also gives us the opportunity to learn from the past in order not to re-live it. And one thing that ought to have been learnt is that the isolation of scientific and other intellectual pursuits, particularly from bodies which claim to be representative, profits no-one and is a futile gesture in the face of strong regimes.

There is another reason why the politicisation of science is particularly inappropriate at present. If voting in United Nations bodies were regularly to divide broadly such that developing countries, with their built-in majority, were able to force the pace against the developed countries which supply the money, then it is not inconceivable that an issue could arise on which the developed world decided it had had enough and would keep its money to itself. As yet there is no sign of this, but UNESCO is bound to be particularly closely watched in the coming year with its new Director-General, Mr M'Bow from Senegal, representative of the shift of power towards the developing countries. He will need to pursue a diplomatic path, and will not be helped by divisive confrontation.

But lest it be said that we are defining divisiveness as that which comes from the developing world, it should be added that some of the initiatives of the developed world seem only capable of generating bad feelings. Massachusetts Institute of Technology, which is negotiating a development contract for water resources in Saudi Arabia, is, it is reported, threatening that any act of religious discrimination will cause the contract to be cancelled. Saudi Arabia can hardly welcome Jews with open arms; it surely behoves MIT to use restraint and not to trigger confrontation by insisting on sending them. □

Some progress on the law of the sea

An indication of the slowness of the rate of progress at Geneva in the Third UN Conference on the Law of the Sea is the fact that at least two more sessions are now envisaged; the next will be convened in a year's time at UN Headquarters in New York. Little likelihood is therefore seen of an acceptable convention being hammered out before the end of 1976 at the earliest and it could not possibly come into force for at least two years after that. Progress has definitely been made, however, not least with the proposals covering scientific research.

DELAY has its dangers and there is still a strong possibility of a complete collapse of the negotiations on the law of the sea, which would be disastrous for developed and developing countries alike. Appeals have once again been made for countries to resist the temptation to take unilateral action before agreement is reached, though the patience of some of them is wearing thin and each year is likely to see further arbitrary claims being placed on statute books by geographically advantaged countries, such as the Latin American States, the USA and Iceland, followed by Canada, Mexico and Norway. Fortunately most nations are, so far, showing definite signs of restraint in staking their claims.

One of the chief stumbling blocks to negotiation is the multiplicity of groupings. It is not a case of two groups of states, 'developing' and 'developed', with clear negotiating positions. There are the geographically-advantaged (Argentine, Brazil, Canada, Kenya, the UK, the USA, and so on) and the geographically disadvantaged (led by The Netherlands), the coastal and the land-locked, the shelf locked, the island states, the archipelagic states and so on, all with different needs, wishes and ideas; each grouping overlaps inextricably with the others. There is little doubt that time is on the side of the geographically advantaged states—the concept of the 'Common Heritage of all Mankind' has been severely mauled and is unlikely to survive, except in a very weak and hardly recognisable form; this is mainly because of the activities of geographically advantaged developing states, rather than developed ones, though Canada has been conspicuously present at the kill.

Negotiating should now start in earnest both in the inter-sessional period and at the next session, though the stated likelihood of a further session after New York "if needed" in summer 1976 will tend to discourage such a move. Three weeks before the end of the conference, however, the chairmen of the three committees were asked to prepare an informal single negotiating text to serve as a procedural device to provide a basis for negotiation. This appeared on the last day of the session and, following scenes of copy snatching from other delegations' pigeon holes, the delegates departed to reconsider and reformulate their positions in preparation for the next occasion. It is vitally important that countries accept this text as a basis for negotiation; if they do not, there is little hope to be seen for any agreement in the foreseeable future.

Countries are still tending to wait for the so-called negotiating phase and, as a result, statements in public often differ quite considerably from the views put forward by the same delegate informally outside a meeting. One of the most surprising positions is that of India, which has in the past benefited almost more than any other developing country from international marine scientific research projects such as the International Indian Ocean Expedition but has been one of the leaders (in public) of the hardliners against any compromise on scientific research in the oceans. There should, in India's view, be no scientific research without very close control by the coastal state or an international authority.

The right to carry out marine scientific research suffered so much from a number of strong statements both for and against that the Chairman of the US Delegation (which came in for praise for the flexibility of its approach to the conference) stated in his closing statement, "I am particularly dismayed by continuing attempts to place restrictions on the conduct of marine scientific research. Knowledge of the oceans is important to all of us. Good science is free science; it is not a commodity that can be packaged and purchased in predetermined quantities. The conference should concentrate on means to ensure that all will enjoy the fruits of science, not on means to restrict science for fear it will only benefit the few".

Shortly before the end of the conference, and it was almost as if this document had not been noticed by the USA (or perhaps the Chairman of the Delegation had finalised his statement by then), a most unlikely group of developing countries, led by Mexico, which country has shown throughout an excellent grasp and understanding of the problems involved, presented a highly skilled compromise document entitled Draft Articles on Marine Scientific Research. This document has avoided most of the pitfalls which have proved unacceptable to one faction or another and should provide a real basis for the relevant part of the convention. Certain of the articles are, however, likely to be used by the developing countries as negotiating elements for improved arrangements for Transfer of Technology, including training and education in the marine sciences.

One of the strengths of this text is the way in which the controversial matter of fundamental as against resource-related research, has been dealt with. The onus is now placed on the coastal state involved to decide under which category an outsider's research programme falls. No doubt something like 90% of marine research will fall in the resource-related category but rules for conduct of such research, with the full consent and participation of the coastal state, are also provided for.

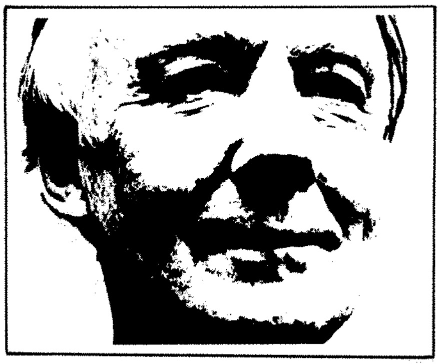
Unfortunately the author of the informal single negotiating text had failed to appreciate this approach and had gone back to some of the earlier, less informed proposed texts which call for the promotion "through competent international organisations of the establishment of criteria and guidelines concerning the differentiation between research directly related to the exploraion and exploitation of the living and non-living resources and fundamental research which is not directly related to exploration and exploitation of such resources"—a virtually impossible task. This text also still contains the fundamental error of linking exploration and exploitation, two completely different activities which should have separate regulations governing them. The former should be encouraged by all, in particular the developing countries, the latter clearly needs close supervision to ensure that any consequent profits are equitably distributed, that renewable resources are not destroyed in the process, that coasta states' rights are fully taken into account and so on.

The other bright spot in the conference has been the work done by an informal group chaired by Minister Jens Evensen of Norway which has developed a series of texts of draf articles on the 200-mile economic zone This group of senior delegates from about a third of the countries presen has had to deal with many diverse matters and interests, such as full use o fish stocks, size of allowable catches historical rights, access to resources by other countries and so on. These wil all be used as negotiating points in what will probably be the key to the convention, as most developing countries are more interested in immediate benefits which are seen to lie in their economic zones than more distant and less identifiable goals. No agreement on the economic zone will mean no convention. So far, however, the landlocked countries, which consist of two factions — those from Europe (like Switzerland and Austria) and the dozen or so from Africa—and the geographically disadvantaged states, consider that their interests have not yet been sufficiently taken into account.

Far more sinister are the activities proposed in the negotiating text for an International Seabed Authority. For instance, under a paragraph entitled "Contracts for Associated Operations", it says, "the Authority may enter into a contract, joint venture or any other such form of association, for the conduct of scientific research, or for the carrying out of a general survey or exploration of the Area . . . " It seems that under these plans the authority would have the right to deny access to the sea bed or to charge heavily for it. The structure proposed in the draft articles for the authority would be large and costly; in fact, it would virtually amount to the setting up of another new UN body which, in the present economic climate, many countries are determined to avoid. Certain of these countries would be prepared to see an authority formed provided it was self-supporting; that is, if its costs were covered by its income from contracts and exploitation licences. The most optimistic estimates are only for three or four contracts a year in the internatinal zone for the foreseeable future and this would certainly not maintain an authority of the size envisaged. Almost certainly the conference will soon start to look to the existing UN bodies, to see if one of them, such as the Intergovernmental Oceanographic Commission (IOC) or the Inter-Governmental Maritime Consultative Organisation (IMCO), could be expanded to take on additional tasks or if a new grouping could be formed.

It is clear from the Geneva manoeuvrings and deliberations that the chief interests of the developing countries lie, quite rightly, in the exploitation of living and mineral resources in the economic zone and in Transfer of Technology. Marine scientific research, instead of being called for urgently, is looked on with suspicion by countries who should know better and is being lumped with such matters as Coastal State Control of Ship-generated Pollution, the setting up of the International Sea-bed Authority for the International Zone, and numerous other matters of lesser interest which will be used as bargaining counters for immediate benefits. □

KENNETH MELLANBY



Weather vein

It is a common experience that when a subject which has previously caused us little concern comes to our serious notice, we seem to find ourselves hearing about it repeatedly. In my own recent experience, climatology is such a subject. In February this year I went to the island of La Gomera in the Canaries, to advise on possible agricultural and other developments. My remit was that developments should not adversely affect the ecology of the environment and should, if possible, encourage native flora and fauna.

La Gomera is nearly circular, some 12 miles in diameter, and it rises sharply to a height of nearly 6,000 feet in the middle. The highest land is covered by the remains of the original forest, most areas have been terraced and cultivated (though many farms have been abandoned) and the population is decreasing. For some years the weather has been unusually dry, and this February—at the end of what should have been the wet season, though little rain fell—the land was parched except where there was irrigation and the tanks, intended for use during the dry summer, were empty.

There are undoubtedly substantial water deposits on the island, but we do not know their capacity, nor how long they will be able to continue to supply fresh water before this is seriously contaminated with salt from the surrounding and underlying seawater. With a good rainfull, such as occurred fairly regularly until recently, the deposits were recharged.

A local consultant is optimistic, claiming that the sunspot cycle will ensure adequate rain in the next 18 months. Other experts are not so sanguine, however. To make a rational plan, climatological information is desperately needed. On it depends the future for the local farmers as much as that for those concerned with a very interesting and unusual development. La Gomera is only a tiny island, but it does epitomise a problem affecting vast areas in many continents, not least those of the Sahel area in adjacent Africa.

I had this example in mind when I attended a recent forum on "Neglected Research", where I heard how the pioneer work of Professor H. H. Lamb's Climatology Unit in the University of East Anglia had been completely denied support from any of the research councils. Yet when I was working on the water problems of La Gomera, I found that expert opinion, not only in Britain but also in other countries, always came back to the recognition of our current ignorance, and to the long-term importance of the work being tackled at Norwich by Lamb and his colleagues. It is difficult to understand why support is denied to a unit concerned with such an important and practical problem area, in which there is a good chance of some success.

It is generally believed that we in Britain have evolved the fairest and least corrupt method for sharing out research funds, even if it is so time-wasting. Many of our most eminent scientists sit day after day on the committees which make the recommendations on how grants should be given or withheld. This thankless task is carried out with care and, if possible, without undue bias. It would be cynical to suggest that those who give up so much of their time do so, partly, because this increases their chances of securing a substantial sum for their own work or for that of their department. It is true that we read in the minutes—"Professor Blank retired during the discussion of this item"—and then, surprise, surprise, follows the announcement that Blank's application for £50,000 has been successful. After all, Blank was put on the committee because of his expertise, and he would obviously not put forward a silly proposal! And occasionally a member's application is turned down. Yet the Lamb incident shows that our situation is not perfect. Even more serious, many unsuccessful and trivial research proposals do receive substantial support, and there is little to show for it.

In a field like research where chance plays so large a part, the very care with which we approach the problem may be a cause of its imperfections. I know, from my own experience, that one of the most substantial grants which led to marked research productivity was given on the whim of a minister and not on the advice of an expert committee. The trouble today is that such large sums of money are involved that we tend to build in complications which may waste much of that money. We forget that original research was once comparatively inexpensive. A plea for more small grants for unfashionable studies might produce unexpected results. □

international news

Soviet seminars are growing

from Vera Rich

Voronel: new development

THE Moscow Sunday seminars are more than a stop-gap for *refusnik* scientists awaiting a visa for Israel. According to their founder, Professor Aleksandr Voronel, who has recently been lecturing in the USA and Great Britain on the international implications of the seminars, they mark an important new development in Soviet science—the establishment of an "alternative" scientific community, which may well have considerable importance for world science as a whole.

When the original fifteen mathematicians and physicists met for the first such seminar in 1972, one of them, Professor Veniamin Levich, joked that it reminded him of his youth, to be back in a group who spoke of nothing but science. This, says Professor Voronel, pinpoints the position of "official" science in the Soviet Union, where, according to orthodox political thinking, "science cannot be non-Party, but must serve some political end". Although few scientists probably hold this view seriously, anyone who wants to go on quietly living and researching in the Soviet Union must at least subscribe to it formally, and, accordingly, meetings of official scientific bodies, from the Academy of Sciences downwards, cannot be conducted in a spirit of pure scientific enquiry, but will inevitably have some political overtones.

Accordingly, when, one by one, the *refusniks* were dismissed from their jobs, in spite of all their difficulties, they found themselves, for the first time in their professional careers, in the ideal state of "scientific detachment". Accordingly, the seminars began to attract not only would-be emigrants and Jews, but other scientists such as Yurii Orlov, Andrei Tverdokhlebov, Valentin Turchin, and Academician Andrei Sakharov. Some members of the group, although wishing to emigrate, have not, as yet, been dismissed from their posts. In spite of a certain turnover in the membership as some participants at last received their visas, the membership has steadily grown and, as at now includes more than 50 people, including 8 professors and 20 Candidates of Science (PhDs). In addition to the main Moscow group, there are members in several other cities who travel to Moscow when papers of particular interest to them are scheduled.

In spite of official attempts to crush the seminar (including, in Professor Voronel's opinion, the *volte face* of the emigration authorities in granting him an exit visa, and recent harassment of the leading members) it now exists as "a scientific community with a good tradition, independent of official organisations and of official policies". This, Voronel says, is a new and important development in Soviet Science, and he urges that western scientists should do all in their power to assist it.

Except in particular cases, such as psychiatry, in which scientific practice is distorted to accord with political theories and aims, he is opposed to any policy of a western boycott of Soviet science. A boycott, he says, may be "more high-principled", but is far less productive. It is not the scientists themselves who are responsible for Soviet science policy, but the officials, and the more contacts which can be established between western scientists and their Soviet colleagues, the better.

It is necessary to distinguish, howver, between what Professor Voronel calls "free" and "monopolised" contacts. A regular feature of almost every international congress or conference to which Soviet scientists are invited is the arrival, not of the expected delegate, but of some substitute appointed not on the grouds of academic merit but for reasons of political expediency. In such cases, Voronel's message is clear: accept no substitutes. If the expected delegate fails to arrive, then a boycott of his replacement's lecture will effectively stress the desire of western scientists for free exchange and their refusal to be dragooned by Soviet planners.

In so far as "free" contacts can be established, however, Professor Voronel is all in their favour. Although his attempt to hold an International Seminar in Moscow in 1974 was effectively broken up by the authorities, who arrested and hounded the leading members of the group and refused visas to the foreigners wishing to participate, contact between the seminar group and western scientists can still, he maintains, be accomplished. He suggests that any scientist visiting Moscow for an "official" conference, should, on a Sunday, make every possible effort to detach himself from the formal programme, and make his way to the seminar. Such a visit, he says, would not only be of interest to the scientists themselves, but would also be a significant statement in favour of academic freedom. Since, at present, Soviet policy favours detente and scientific cooperation (at the official level), the chances of a resolute scientist actually getting to the seminar should not be viewed too pessimistically. At the moment the authorities "have to be patient" with visiting scientists, and although, one presumes, the crucial time would be carefully filled with some other function or activity, he is convinced that, with determination, it should not prove impossible.

Meetings normally commence at noon, and details of venue and programme may be obtained from the seminar secretary, Professor Brailovskii. His address is Vernadskogo Prospekt 99, Block 1, Flat 128 (close to the Yugo-Zapadnaya metro station). Unfortunately, as part of the general policy of discouraging participation in the seminar, Professor Brailovskii's telephone was cut off some time ago.

Voronel stresses that such "free contacts" will not only benefit the *refusnik* members of the seminar, eager as they are to maintain an exchange of ideas with other scientists. Such meetings, he says, will benefit the whole concept of scientific exchange with the Soviet Union. All Soviet scientists, not only would-be emigrants, need contacts, scientific freedom, and the free exchange of ideas. within the framework of the whole Soviet scientific community, the seminar is important

Chemical plants on the doorstep

by Allan Piper

FOLLOWING the publication on May 12 of the report of the Court of Inquiry into last year's explosion at the Nypro chemical plant, the inhabitants of the villages around Flixborough are not alone in their misgivings over the report's assertion that "the siting of the works . . ." (in a sparsely populated area) " . . . was fortunate". Residents of the densely populated London boroughs of Ilford, Newham and Barking, who also live in the shadow of a chemical factory which formerly manufactured, and still stores, cyclohexane, are awaiting the outcome of an inquiry into a recent accident at the factory.

The accident, which resulted in the death of a 52-year-old worker, occurred on April 5, 1975, when the plant used in the manufacture of sorbitol exploded in the Ilford factory of Laporte Industries, a British-owned chemical company. The inquiry into the Laporte incident is the first to be ordered by the newly formed Health and Safety Commission whose involvement lends a wider interest to a continuing dispute over the siting of chemical plants that had already developed between the factory management and anxious local residents.

Laporte Industries moved to Ilford in 1961 after taking over the factory from a small pharmaceuticals company and since the move phthalic anhydride, cyclohexane, and sorbitol have, at various times, been manufactured there. Ever since the arrival of the company local people have been concerned about the standard of safety regulations enforced within the factory, claiming that the company has, until recently, acted less than openly with them. In spite of official assurances that everything possible is done to maintain satisfactory safety standards several incidents had occurred before the latest accident.

In 1969 part of the plant used to manufacture phthalic anhydride exploded. After the Flixborough disaster last June it became known that earlier the same year a small fire had broken out in the cyclohexane plant in Ilford. This was the first time that the residents became aware of the dangers posed by the manufacture of cyclohexane. Although the process was only being operated on a tenth of the scale of that at Flixborough, the Ilford factory is situated in a densely populated area and backs immediately on to a primary school of 650 pupils. Though cyclohexane and phthalic anhydride are no longer manufactured there, both chemicals are still stored there in large quantities.

Local concern led to the formation last year of a tenants' association, the Roding Environmental Safety Campaign (RESC), which is pressing Laporte to provide details of all hazardous processes operated at the factory and wants to see acceptable safety standards implemented at all plants.

But open days held at the factory last year were not reassuring. Neither is the RESC happy about the circumstances under which the cyclohexane plant was permanently shut down last October after a visit by the Factory Inspectorate. In their annual shareholders report, however, Laporte maintain that the closure was purely in deference to the understandable apprehension of local residents and was unconnected with the visit.

The worker who died in April was severely splashed with caustic potash solution following an explosion in a hydrogen plant used in the manufacture of sorbitol. The Factory Inspectorate are said to have visited plant associated with the hydrogen plant only a few weeks before the accident. Furthermore, the RESC claim to have understood from the company that sorbitol was a "safe" chemical and were not informed that part of the manufacturing process involved some risk.

The RESC has already pressed Parliament for a public enquiry into the running of the factory and a consideration of the siting of dangerous processes in the area. On April 11 Dennis Howell, the Minister of State for the Department of the Environment, expressed a willingness to help but on the question of siting he pointed out that "the Laporte factory was there before the houses and the school were erected, and not the other way round".

The RESC have at least obtained some backing from Redbridge Council who said earlier this month that they would continue to press Michael Foot, the Minister responsible, for a public enquiry into the safety of the works. In the same statement they also referred specifically to enquiries being conducted into the recent accident and said that the Factory Inspectorate had agreed to meet both the Council and the RESC to discuss the inquiry report following its publication.

Whether or not such discussions ever take place will depend entirely upon the Health and Safety Commission: the commission has stated that it would be left to them to "decide whether or not a report is to be published". Though officially they may not allow such a decision to be swayed by matters outside the incident under investigation it is unlikely that they will miss the opportunity to set a healthy precedent. □

---

as a forum for scientific exchange independent of government and party policy.

The current atmosphere of détente lays considerable stress on scientific contact and exchange. The Soviet authorities, however, says Professor Voronel, wish to monopolise these contacts. Whether the recent flood of scientific and technological cooperation agreements which the Soviet Union has been signing will result in a genuine exchange of scientific opinions and information, not to the benefit of any one country, but to that of science as a whole rests, says Voronel, not with the politicians, but with the scientists. Now is the crucial time, he stresses, for western scientists to establish "new conditions and forms of contact" with their Soviet colleagues. □

Manpower planning and higher education

by Eleanor Lawrence

MANPOWER planning should have a greater part to play in decisions about the future expansion of British universities and polytechnics, according to Lord Crowther-Hunt, Minister of State overseeing higher education.

Speaking at a conference in London last week, he said that "at a time of economic and financial difficulty we need to be more than ever certain that the money we spend is well spent". He emphasised that "it simply will not do to allow universities and polytechnics to produce whatever people they fancy or to relate the number and kind of places they provide to the applicants that come forward". This was a passive approach which ignored policy variables which were in fact at the disposal of the government.

Undeterred by the admitted lack of success of previous efforts to forecast manpower demand, Lord Crowther-Hunt said that he wished to pursue a "positive approach to higher educated manpower, both to look again at what might be the needs of the economic system and to ask questions not simply about numbers of qualified people but the nature of the qualifications".

The Government could influence the situation in several ways, said Lord Crowther-Hunt. "At the one extreme, student grants and the counselling services of schools can surely affect the demand for places in higher education. At the other a considerable fraction of all graduates end up in public service. It follows that the size of the public sector and the qualifications demand in the public sector will themselves help to determine the number and kinds of graduates we need. It seems to me therefore that it is most unlikely that the best policy for a Government in the long term is simply to observe and to accept whatever is happening", he said.

- Hinting at further economies in the higher education system, Lord Crowther-Hunt dealt with the place of research in the universities in a speech to the Association of University Teachers in Manchester last Friday. About a quarter of university expenditure went into research, he said, which involved about one student in five.

"We all know of postgraduates in our universities who are neither contributing to the advance of worthwhile knowledge nor even adding in any worthwhile way to their qualifications", he said. "Does too much of our effort go into postgraduate work? Should there be a shift of emphasis to undergraduate education and teaching? Just as we have to become more efficient in industry, so do we in education". □

THE theme of this year's International Telecommunications Day, May 17, was "Telecommunications and Meteorology". This was also the theme of World Meteorological Day, March 23. Therein lies a story of real collaboration between two UN agencies which could set a pattern for the future.

Certainly the theme chosen is one that could hardly avoid involving both the agencies concerned—the International Telecommunications Union (ITU) and the World Meteorological Organisation (WMO). The important point is that it was chosen deliberately, the collaboration was intended and the celebrations planned jointly from the start. There are, it is true, a number of factors making it comparatively easy for these two agencies to work together. And each has been in existence long enough to be much more relaxed in its approach and, perhaps for that reason, rather more efficient in its operations than are its bigger brethren.

The trouble is that the large postwar agencies such as the FAO, UNESCO and the WHO tend to regard themselves as autonomous organisations advising—and at times seeming to pressurise—their member governments, rather than servicing them as do the ITU and the WMO. These big boys of the UN family have a certain arrogance that makes close collaboration difficult, not only among themselves but also with the smaller agencies. The latter feel swamped by the huge input that an agency such as UNESCO can allocate to a collaborative project or contribute to a meeting—and irritated by the way in which the same agency may take all the credit, even when the smaller, more expert body has done most of the planning and provided the greater part of the technical expertise.

The agencies do, of course, work well together on specific issues. But in dealing with wider issues—such as the problems relating to the world's water resources, which involves the FAO, UNESCO, the WMO, the WHO, the UN itself and now the United Nations Environment Programme (UNEP)—chaos still tends to reign. The apparently inevitable tendency of any new body to indulge in empire-building, of which the UNEP has in less than two years provided an already notorious example, makes matters worse.

In 1979 or 1980, one understands, it is planned to hold a major UN conference on the role of science in development. Is it too much to hope that, given four years in which to plan it, this may provide a real example of how UN agencies, almost every one of which is concerned in the application of science at one level or another, can collaborate for their own and everyone else's benefit? *from Peter Collins*

Plenty of potential for jojoba oil

by Colin Norman, Washington

IT sounds too good to be true. An unprepossessing desert shrub, now growing wild in parts of Mexico and the south-western United States, could, potentially, help save the sperm whale from extinction, rescue a number of Indian tribes from grinding poverty, and supply the automobile industry (among others) with a valuable raw material that is at present unavailable. The catch, though, is that it would take considerable capital investment and several years of effort to convert that potential into reality.

Nevertheless, a committee of the National Academy of Sciences last week enthusiastically urged the federal government to help underwrite the costs of cultivating the shrub on Indian lands. The committee suggested that plans should be set up immediately for establishing 400 acres of plantation a year over a five-year period.

Known as jojoba (pronounced 'hohoba'), the shrub produces peanut-sized seeds which contain about 50% by weight of a colourless, odourless oil. Its economic potential lies in the fact that the oil is unique among vegetable oils—it closely resembles sperm whale oil and when hydrogenated forms a hard wax which has a number of commercially promising features.

In 1971, the federal government banned use of sperm oil and other whale products in the United States because of the creature's threatened extinction. That move threw the automobile industry into a fit because sperm oil was considered essential for lubricating automatic transmissions. It has unique properties which enable it to withstand high pressures and temperatures,—and frustrating experiences with mineral oil substitutes which have been developed since 1971 attest to its value.

If jojoba turns out to be a good replacement for sperm oil, at the right price, it could rapidly be in high demand. Moreover, if the hydrogenated jojoba wax could be used as a replacement for spermaceti, which is also banned, or carnauba wax, which is now imported from Brazil at record prices, its economic potential would be even further enhanced.

To see whether the material is indeed as promising as people had been claiming, a research project directed by the University of Arizona's Office of Arid Lands Studies and the University of California at Riverside was begun in 1972. To start with, 87,000 pounds of jojoba seeds were harvested from wild shrubs by Indians in California and Arizona, and jojoba oil was farmed out to more than 75 corporations and research institutes for testing. It was the results of those tests, and of parallel tests carried out in Israel, which led to the enthusiasm displayed last week by the committee of the National Academy of Sciences.

The committee's report was intended as a general scientific survey of jojoba oil, and another committee is now taking a close look at the economics and the agricultural aspects of jojoba cultivation. Nevertheless, the report concluded that the evidence is sufficiently promising for the government to subsidise cultivation and an expanded research programme.

Chemical analysis of jojoba oil has confirmed that is it strikingly similar in composition to sperm oil. Both consist of wax esters, with similar chain lengths and an almost identical number of double bonds. And mechanical tests demonstrated that "jojoba oil can duplicate sperm oil performance as a high pressure lubricant".

As for the wax derived by hydrogenerating jojoba oil, the committee concluded that it has properties almost identical to those of carnauba wax. At present, carnauba wax, which is laboriously scraped from the fronds of palm trees, is imported into the United States entirely from Brazil. If hydrogenated jojoba oil could be developed into a domestic wax source, immune from the vagaries of international commerce, US industry would be assured of a continuous supply of uniform quality.

A key factor in the future for jojoba oil, however, is that the shrub could be grown on Indian reservations in the south-western United States, and it could provide a basis for some tribes to become economically self-sufficient. At present, many tribes in the area are living in conditions of extreme poverty.

The problem, however, is that it would be costly to establish plantations, and since it takes on average five years for the shrubs to start producing seeds, return on the investment would be slow. For those reasons, it is unlikely that industry will move rapidly into jojoba cultivation, and federal government funds will be needed.

According to experience in California, where 34 acres of jojoba were planted in 1974, start-up costs would be between $1,500 and $2,800 an acre. The most expensive part of the operation would be clearing and irrigating the land. But, once established, it would cost only about $100 an acre a year to maintain the plantation and to harvest the seeds. And, since jojoba bushes live for between 100 and 200 years, the initial investment would have ample time to pay off.

Studies have shown that cultivated jojoba bushes would produce, on average, 5 pounds of seeds, and a plantation would yield between 1,000 and 2,000 pounds of oil a year. Since sperm oil sells at about 40 cents a pound in those countries which still allow it to be marketed, and carnauba wax retails at about $2 a pound, the committee notes that " it can be seen that returns per acre from established jojoba plantations would be substantial."

Is it possible to predict with certainty that the oil would be in high demand if it were produced? The strict answer is no, but industry has so far shown sufficient interest to justify a qualified yes. Dr Demitrious M. Yermanos, Professor of Agronomy at the University of California, Riverside and a member of the academy committee, noted last week, for example, that jojoba oil has never been available in sufficient quantity for it to be market-tested. But he predicted that once it becomes available in quantity, industry will be very keen to use it. ☐

correspondence

Naples Zoological Station

Sɪʀ,—Some time ago (January 18, 1974) you published an interesting note on the Naples Zoological Station, which expressed the concern of the biological community about the future of the station and considered the importance of its future leadership as well as the question of maintaining international participation in its life and activities.

Since then there have been several changes and we should like to tell you how things stand at present.

After the increase of the annual budgetary support by the Italian government, the new set of statutes has been implemented. Consequently, we have seen the end of the seven-year-long "provisional Administration" and the formation of a new Council of Administration and an Executive Committee. A seat on the new Council of Administration is open to any country or institute that contributes more than £40,000 a year; such participation is seen as one of the most effective ways of strengthening and making more formal the international nature of the scientific collaboration that has been a main feature of the station for more than 100 years. We should very much like to think that Britain will have a seat on the new council.

To complete the new organisation of the station, we now need to appoint a Scientific Council (four members of which must be chosen from among foreign biologists, and one of these four by the International Union of Biological Sciences), and a director. It is hoped that these appointments will be made shortly.

Yours faithfully,

A. Bᴀʀʟᴀᴀᴍ

Naples Zoological Station

Leprosy

Sɪʀ, — Most voluntary agencies in Europe engaged in leprosy work are members of the International Federation of anti-leprosy Associations (ILEP) which brings together 22 member-organisations, of which 18 are European. The field of action of the federation extends to some 600 centres or projects in 75 countries afflicted with leprosy. According to the last statistical data available (1973), the federation is helping 1,106,560 leprosy patients, thus representing an important section of the voluntary agencies engaged in the world-wide anti-leprosy campaign. Among all the leprosy patients under treatment in the world, one out of three is aided by the federation. 96% receive domiciliary treatment and only 4% institutional care, as leprosy control is the top priority of the federation, in accordance with the WHO's policy. The total financial help provided by the member organisations is more than £4 million per year. More than 5% of the total budget is spent on research in leprosy (about £360,000 in 1974).

I hope you may consider this as an answer to the following sentence appearing in an article published recently (*Nature*, March 20): "Voluntary agencies in Europe collect more than £2 million annually for leprosy work, but most is still spent on institutional care".

Yours faithfully,

P. Vᴀɴ ᴅᴇɴ Wɪᴊɴɢᴀᴇʀᴛ

ILEP, 8000 Amiens,
France

A hundred years ago

The subject is treated of under three headings: General Dietetics, Special Dietetics of Health, and Dietetics in Sickness. The author commences with the question—What is the natural food of man? Flesh-eating animals have teeth, jaws, and limbs suitable for capture and tearing, vegetable feeders have bulky viscera, and so on. Applying similar arguments to the human race, "to judge by form and structure alone, the natural food of an adult man must be pronounced to be *nothing;*" from which we must necessarily deduce, as is indicated by other considerations, that man as man assumed his special characters *after* he commenced the employment of instruments for offence and defence. In fact, the developed heel, with which is correlated the non-arboreal habit, is incompatible with the naturally defenceless condition of our species.—from a review of Dr Chambers 'Manual of Diet'.

from *Nature*, **12**, 64; May 27, 1875.

news and views

Early man in the New World

from G. E. Kennedy

THE question of man's antiquity in the New World has been the source of long and often acrimonious debate. The matter has polarised around two widely differing points of view. An ultra-conservative approach, first developed by Holmes in the 1890s and brought to full culmination by Hrdlicka in this century, was based on two premises: that man was a relatively recent immigrant to the New World and that all Amerindians were of Mongoloid racial type. Hrdlicka was especially effective in destroying any claim to an early arrival of man in the New World and the vigour of his opposition had an almost paralytic effect on the early development of Palaeoindian studies. The conservative viewpoint, scepticism now tempered with careful scholarship, has continued in the work of Haynes, Irwin and others who maintain that empirical evidence of man in the New World prior to about 12,000 BP is very tenuous. The alternate viewpoint accepts considerable antiquity for man in the Western Hemisphere. Workers such as Wormington, MacNeish and Krieger, for example, while properly maintaining that many claims of great antiquity are spurious, have pointed to some early dates which are, in fact, very difficult to dispute.

The evidence of man's occupation of the New World prior to about 12,000 BP falls neatly into two categories: archaeological evidence and human skeletal evidence. Unfortunately, the association of tools and human remains occurs at very few early sites. The Yuha site in southern California, dated at 21,500 BP ∓2,000 (Childers, *Anthrop. J. Can.*, **12**, 2; 1974) and the Marmes Rock Shelter, in Washington state, dated to about 13,000 BP (*Fryxell et al.*, *Am. Ant.*, **33**, 511; 1968) are two of the very few early sites where such associations occur.

George Carter, whose archaeological work has centred mainly in southern California, is one of the leading proponents of great antiquity for man in the New World; he has suggested that stone tools from the Texas Street site, in San Diego, for example, possibly date to the last interglacial (*Pleistocene Man at San Diego*, Baltimore, 1957). His claims have been widely disputed and most archaeologists consider that the Texas Street 'tools' were formed by natural rather than human processes. The Calico archaeological site, in the desert east of Los Angeles, has been claimed to demonstrate evidence of human occupation at about 50,000 to 80,000 years ago and dates of 120,000 years ago, based on geological evidence, have also been suggested (Leakey, Simpson and Clements, *Science*, **160**, 1022; 1968). Evidence has been put forward at Calico to support the existence of one and perhaps several hearths deeply buried in an alluvial fan. Though the human origin of the 'hearths' has been questioned the interpretation, as tools, of flaked and chipped lithic material from the site is very difficult to dispute. Conclusions regarding the Calico site should await a more comprehensive study of the lithic materials than has been undertaken so far. Other early sites, from Canada to South America, show artefacts of unquestioned human design in firmly dated contexts. The Lewisville site, in eastern Texas, comprises more than 21 hearths which, in many cases, contain the burnt remains of now-extinct Upper Pleistocene fauna; charcoal from two of these hearths has been dated to more than 37,000 years (Crook and Harris, *Am. Ant.*, **23**, 233; 1958). On Santa Rosa Island, off the southern California coast, burnt mammoth bone has been dated to 29,700∓3,000 (L290R, Broecker and Kulp, *Science*, **126**, 1324; 1957). Other material, obtained from a fire area on the island was reportedly beyond the range of radiocarbon dating (UCLA 749, Berger and Libby, *Proc. natn. Acad. Sci. U.S.A.*, **56**, 1678; 1966). A recently reported site from the Old Crow River basin in north-eastern Canada has yielded a worked caribou tibia dated to $27,000^{+3,000}_{-2,000}$ (Irving and Harington, *Science*, **179**, 335; 1973). One of the most indisputable of the palaeoindian tool sites is in the Ayacucho Valley of Peru; here, in a deposit underlying a level with a radiocarbon date of 19,600 BP ∓3,000, MacNeish has found stone tools in association with the bones of Pleistocene fauna (*Scient. Am.*, **224**, 36; 1971). On the basis of the early occurence of this "core tool tradition" in South America, MacNeish has suggested that man may have entered the New World as early as 100,000 years ago.

In the analysis of human skeletal material, the field of Amerindian palaeontology is still in its infancy, in spite of nineteenth century origins. Very little early human material is known and of that material provenance and associations are sometimes unsure. With a few notable exceptions none of the very early material has been completely described and without exception none of this early material has been analysed within the statistical framework of population theory. Such treatment, in a comparative context, is vital if we are to gain objective insight into the origins and relationships of the earliest Amerindians.

Of the human material that is available, the child's remains from Taber, Alberta may have present claim to the greatest antiquity; stratigraphical evidence suggests that the site is more than 37,000 years old and may be as much as 60,000 years old (A. Stalker, *Am. Ant.*, **34**, 425; 1969). The racemisation dating technique has been of considerable importance in placing many specimens, long undated, in a chronological framework. The earliest of the racemisation dates has been obtained from the 'Del Mar' skull; this nearly complete cranium from southern California has been dated to 48,000 BP (Bada *et al.*, *Science*, **184**, 791; 1974). A frontal fragment from the same area has been dated to 44,000 BP and a potentially important group of post-cranial material has been dated at 28,000 BP (*ibid.*). This latter material, however, recovered 49 years ago, has not yet been cleared from its matrix. The 'Los Angeles Man' cranium has been dated with both radiocarbon and racemisation and these dates are in close agreement: >23,600 in the first case (Berger *et al.*, *Contr. Arch. Res Fac.*, No 12, University of California at Berkeley, 1971) and 26,000 in the latter (Bada *et al.*, *ibid.*). The clear antiquity of Los Angeles Man makes the unaccountable loss of the associated post-cranial material very regrettable. The Laguna skull, also from the southern California coastal region, has been dated to 17,150∓1,470

(Berger *et al.*, *ibid.*).

Although there is no question of the Mongoloid affinities of the modern Amerindians the origins of the earliest groups are not as clear. Some anthropologists consider that the Mongoloid populations of Asia are among the most recently developed of the major human racial groups. Coon and Birdsell, for example, would argue that the Mongoloids developed, as a population, not more than 10,000 years ago. If this is true, then obviously the earlier New World immigrants must have had non-Mongoloid affinities. Birdsell, Hooton, Howells and others have, in fact, detected possible Caucasoid elements in the remains of some early Amerindians and have linked these with Upper Pleistocene populations in eastern Asia; Birdsell has used the term 'Amurian' for these Asian groups. The question of the population affinities of the earliest Amerindians is a complex one and the answer must await further data from both Asia and the New World.

Oddballs and galaxy formation

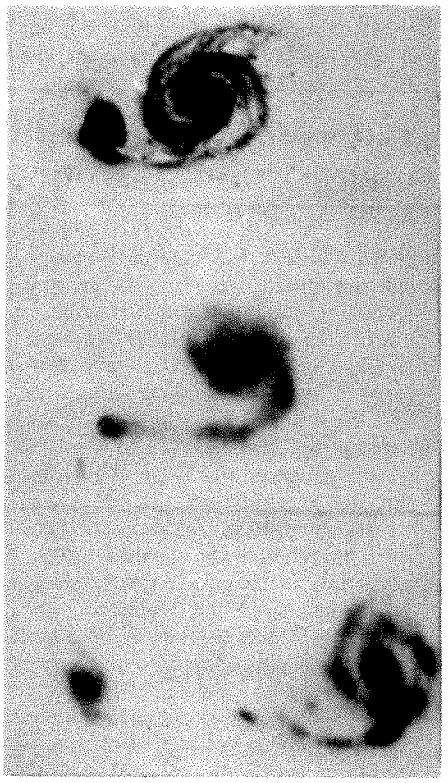
from James Binney

THERE seems to be no limit to the number of weird objects one can turn up in the sky. We now have catalogues compiled by Zwicky, Vorontsov-Velyaminov and Arp, containing over ten thousand peculiar extragalactic objects. These range from almost stellar, highly luminous emission line objects to groups of distorted, apparently interacting galaxies. Many of the objects identified as peculiar on optical plates turn up also as unusually strong emitters in other ranges of the electromagnetic spectrum. Undoubtedly these objects would well reward greater study. Indeed three recent papers suggest that they may be able to teach us something about one of the greatest enigmas of modern cosmology: the formation of galaxies.

Freeman and de Vaucouleurs (*Astrophys. J.*, **194**, 569; 1974) suggest that pairs of an irregular galaxy and a spheroidal galaxy could be produced by the collision of spiral galaxies with an hypothesised intergalactic cloud of neutral hydrogen (see *Nature*, **254**, 181; 1975). Freeman and de Vaucouleurs suggest that the Universe may be filled, not necessarily uniformly, by a few hundred clouds of neutral hydrogen per massive galaxy. If the radii and masses of these clouds lie in a narrow region around 10^5 light-years and 10^9 solar masses they claim one can account for the observed density of spheroidal–irregular galaxy pairs in terms of the compression and fragmentation of the gas involved in the collision of the gaseous part of a spiral galaxy with one of these clouds. Stars formed from this gas would form the irregular or ring galaxy while the stellar component of the spiral galaxy would pass on as a spheroidal system.

This links with the work of Oemler who has concluded from a study of 15 rich clusters of galaxies (*Astrophys. J.*, **194**, 1; 1974) that there are three basic types of rich clusters: spherical ones, like the cluster Abell 2199, which contain an irregular giant galaxy at the centre and are rich in elliptical galaxies, clusters rich in lenticular galaxies and spiral rich clusters. Oemler's work tends to confirm the suggestion of Gunn and Gott (*Astrophys. J.*, **176**, 1; 1972) that the spiral rich clusters are ones in which the general cosmic expansion, though slowed by gravity, has not yet been reversed, whereas the clusters rich in lenticulars are ones where recollapse has occurred and a substantial fraction of the spiral galaxies initially present have been stripped of their disk component in interactions with an intergalactic medium. Could this intergalactic medium consist of the gas clouds of Freeman and de Vaucouleurs? Is it the mass of these clouds which binds the galaxies into a cluster in spite of the very high velocities these galaxies appear to possess?

Another quite different interpretation of some of these multiple systems of interacting peculiar galaxies is argued in a research note by Vorontsov-Velyaminov (*Astr. Astrophys.*, **37**, 425; 1974). Vorontsov-Velyaminov believes he has identified a number of systems caught actually in the act of breaking up into two or more parts, or 'gemmation' as he calls it. The figure for example is taken to show three stages in the ejecion of a satellite galaxy from a late-type spiral galaxy. Though this example could perhaps be more easily understood in terms of satellite capture for which numerical models by Toomre and others exist (*Astrophys. J.*, **178**, 623; 1972), others of Vorontsov-Velyaminov's specimens could well represent small groups of galaxies forming from a large cloud of hydrogen. A fragmentation process of this type has been suggested by Casini *et al.* (IAU meeting, Trieste, September 1974) in relation to Markarian's very similar groups of galaxies.



Proposed stages in ejection of a satellite galaxy from a late-type spiral galaxy; from Vorontsov-Velyaminov, *Astr. Astrophys.*, 37, 425; 1974.

All this tinkering with the population of dwarf galaxies does not of course directly help us to understand the more fundamental formation of giant galaxies like our own. Nothing daunted by the failure of cosmologists to come up with a satisfactory mechanism for triggering the formation of condensed objects in an expanding Universe, Meszaros (*Astr. Astrophys.*, **38**, 5; 1975) has explored the possibility that a primordial population of black holes of about solar mass might have precipitated the much later collapse of galactic masses. He finds that if the total mass of black holes in the present-day Universe were between one and ten times the mass contained in visible galaxies, the statistical fluctuations in the number density of black holes in the early Universe may have caused perturbations in the overall matter density of the Universe to grow from the end of the first 10^{-4}s of our history. These black holes would now be clustered around galaxies in enormous numbers (about 10^{12} around the Milky Way) forming a massive halo of the type whose existence has been suspected on other grounds (Ostriker and Peebles, *Astrophys. J.*, **186**, 467; 1973). Unfortunately the detection of these black holes is well nigh impossible and the physics underlying theories of their formation rather doubtful.

The real problem of galaxy formation remain very much unsolved. The greatest difficulty is that we still have no idea what induced the formation of the first bound objects in an expanding Universe. One suspects that the origin of these local inhomogeneities in the structure of the Universe will be understood only when we know why the Universe is so remarkably smooth and homogeneous on a large scale and a major effort is now going into the possibility that this isotropy is the result of quantum effects back in the period when the Compton wavelength of an elementary particle was comparable with the radius of the then visible Universe. The other urgent task in cosmology is to understand how in the more recent past great masses of gas collapsed to form galaxies and clusters of galaxies. This task is particularly exciting because there is every reason to believe that we should be able to actually see this happening by looking out into distant space. What we require are detailed models of the collapse to enable us to identify a nascent galaxy when we see one.

How to study the birth of galaxies using radio-astronomical techniques

by John Gribbin

If you accept the standard picture, galaxies and clusters of galaxies were formed by condensation from a more uniform distribution of hydrogen gas. But just how hydrogen clouds transformed into galaxies is far from clear, and there has seemed little chance of making the situation more clear by direct observation. Now, however, Sunyaev and Zel'dovich have come up with a suggestion that radio observations might provide a clue to events occurring at the epoch when galaxies were forming in the Universe (*Mon. Not. R. astr. Soc.*, **171,** 375–379; 1975).

Some of the principal questions which are far from being answered are listed by the two Soviet astronomers: Were globular clusters formed first and later joined into galaxies? Did the first step consist of separation and condensation of giant gas clouds (with masses in the range 10^{13}–10^{15} $M_\odot$) which later disintegrated into galaxies, globular clusters and individual stars? At what redshift z (relative to us) did this occur? And what were the density and temperature of the gas clouds from which galaxies formed?

In principle at least, some of these questions might be answered by radio-astronomy studies not hopelessly more sophisticated than those of the present day. One approach would be to search for the redshifted 21-cm hydrogen line emission from the epoch just before galaxies were formed.

Sunyaev and Zel'dovich consider the case of spherical galaxies with mass 3×10^{14} $M_\odot$ and diameter 2 Mpc, separated by 30 Mpc. Making reasonable assumptions about the proportion of neutral hydrogen, H I and He I, and taking the diameter of a cloud just before stars formed as also being typically 2 Mpc, it turns out that the hydrogen line should still be seen as an emission line, even with a redshift of 5–10, if at least half the protogalactic material was in the form of hot gas ($T\sim7{,}000$ K). The increase in temperature of the observed line over the background is, however, only expected to be some 7 K, for an observer co-moving with the protogalaxy.

But to an observer on Earth the line will be redshifted to 100–200 cm wavelength, a region where the overall background has a brightness temperature ranging from 20 to 200 K. Is it sensible to expect to be able to detect the redshifted hydrogen line above this background? The answer depends, of course, on just how many proto-galactic clouds there might be at these large redshifts in each solid angle of sky subtended by the observing telescope. Sunyaev and Zel'dovich conclude that no more than 200 protoclusters might be visible over the whole sky at any one wavelength, and that "observations with a variable wavelength are essential, both in order to augment the number of protoclouds observed and also to distinguish them from sources of different type with continuum spectra".

They also suggest still more complicated experiments, but this one test is likely to be enough to tax the ingenuity of radio astronomers at present. Still, the possible results would seem to merit some effort being made. As Sunyaev and Zel'dovich say, "these observations are very difficult and substantial improvement of existing equipment will be needed to fulfil the task, but the importance of the problem seems . . . to warrant discussion in order to attract the attention of experimentalists".

- **One in a million.** Meanwhile, a reminder to galaxy hunters that not all of the peculiarities of unusual astronomical objects result from physical processes hinting at new universal laws, and that coincidences do happen, has come from a study by de Vaucouleurs and de Vaucouleurs of NGC985—a ring galaxy with a Seyfert nucleus (*Astrophys. J. Lett.*, **197,** L1; 1975).

If ring galaxies do form when normal galaxies collide with intergalactic clouds (as Binney discusses above), and if, as seems likely, some (and perhaps all) normal galaxies experience Seyfert outbursts, it is plausible that the formation of the ring in NGC985 and the presence of Seyfert activity are completely unrelated. De Vaucouleurs and de Vaucouleurs suggest that the probability of a randomly chosen Sa–Sc spiral having encountered an intergalactic gas cloud in the past 5×10^7 yr (so that the ring is still visible) is about 10^{-4}, and that the probability that the nucleus of a giant spiral is seen today in the Seyfert stage is about 10^{-2}. That makes NGC985 literally a galaxy in a million.

Specific response of *Drosophila* cells to heat shock

from Benjamin Lewin

When larvae of *Drosophila melanogaster* are subjected to a heat shock, usually a rise in temperature to 37 °C from the usual 25 °C, a change in the pattern of puffing is seen in the salivary gland chromosomes; preexisting puffs regress and new puffs appear at several, specific sites. The same response is produced by treatment with respiratory inhibitors and occurs during recovery from anaerobiosis. The switch to puffing at these bands presumably represents the expression of new gene functions and, because of the different treatments which elicit it, may perhaps constitute some generalised response to certain environmental abuses of *Drosophila* larvae. The specific puffing pattern can be provoked by heat shock of isolated salivary glands and so must be autonomous. It is not known what functions it represents; but the limited number of bands that is involved and their coordinate expression in response to more than one treatment of larvae or excised tissues suggest that this may be a useful system for investigating genetic control and defining the number of functions in individual bands.

Two recent series of experiments exploit the remarkable observation that heat-shocked tissue culture cells of *Drosophila* seem to display the same response as whole larvae or isolated salivary glands. The cultured cells in both sets of experiments are derived from Schneider's S2 line, originally grown from mixed early embryonic cells, and therefore unfortunately not of well defined phenotype. But the cells' apparently autonomous response implies that the results of experiments with them may be representative of the *in vivo* gene expression of *Drosophila* larvae.

A study of the messenger RNA present in normally grown and heat-induced cultured cells was recently reported by Spradling, Penman and Pardue (*Cell*, **4**, 395–404, 1975). The poly(A)-containing mRNA of the polysomes of these cultured cells shows a very broad size distribution on sucrose gradients, similar to that seen with many cultured mammalian and insect cells. When this RNA is hybridised *in situ* with salivary gland chromosomes, it binds to many loci, apparently representing at least 50 bands on the four chromosomes; in addition there is intense binding at the chromocentre. Of course, it is not surprising that many genes in euchromatin should be expressed; some bands, about a dozen, are more heavily labelled than most and these are seen more clearly by using lower concentrations of the labelled mRNA. This reduction in concentration leaves the chromocentre still heavily labelled, however; the chromocentre seems to include two types of heterochromatin : α-heterochromatin which consists of satellite DNA and is under replicated in the formation of polytene chromosomes, and β-heterochromatin, about which less is known. Since satellite DNA seems to be inert in transcription, these results suggest that α-heterochromatin may contain genetic material that codes for mRNA. Another implication of these results is that a comparatively small number of bands is expressed in the cultured cells, certainly fewer than (say) a hundred. Yet estimates of complexity made from the reaction between mRNA and cDNA or isolated nonrepetitive DNA suggested the expression of a much larger number of genes, of the order of 2,000 (cited in Bishop *et al.*, *Nature*, **250**, 199–203; 1974) Kinetic analysis suggests that most messengers represent genes in nonrepetitive DNA; and genetic analysis suggests that each band specifies a single genetic function This discrepancy is therefore difficult to resolve at present if all the messenger species in the population are able to hybridise *in situ*

A drastic change occurs in the mRNA when the cultured cells are shifted to 37 °C. Within an hour, the broad distribution on a sucrose gradient is replaced by four distinct peaks, in a somewhat similar overall size range When the poly(A)-containing mRNA of the heat-shocked cells is hybridised *in situ* with salivary gland chromosomes, it reacts with only a small number of bands, those that are puffed during heat shock in the larva or excised tissue. This suggests that the same switch in gene expression occurs in the cultured cells as in the intact tissue. The most heavily labelled band is 87C1, and other labelled bands include 63C, 67B, 87A, 93D, 95D. Although very similar to the heat-shocked puff pattern, the hybridisation pattern is not indentical; some bands that puff in larvae, 33B, 64F, 70A, do not hybridise specifically with the heat-shocked mRNA, and band 85A binds mRNA after heat shock but does not puff in larvae. Whether this represents a genuine difference in gene expression between cultured cells and salivary glands or is rather a consequence of different assay systems is not known; however, the same repression of previously functioning bands and almost identical expression of new bands is produced by heat shock in both cases.

Changes in protein synthesis

A start towards identifying the functions of the heat-shock puffs was made last year by Tissieres, Mitchell and Tracy (*J. molec Biol.*, **84**, 389–398; 1974) when they reported that heat shock causes changes in the pattern of protein biosynthesis; synthesis of most proteins is much reduced but synthesis of a small number, about six, is induced. This provides an obvious correlation with the changes now observed in mRNA synthesis. Tissieres *et al.* observed that the principal induced protein has a size of about 70,000 daltons and corresponds to some 20% of the newly synthesised protein. Since the heat-shocked puff that they observed at 87B accumulated newly synthesised RNA the most intensely, they suggested that this protein may be coded by a gene in the 87B band.

Using the Schneider S2 culture line, Mckenzie, Henikoff and Meselson (*Proc. natn. Acad. Sci. U.S.A*, **72**, 1117–1121; 1975) now report that the same changes in protein synthesis, followed by SDS gel electrophoresis, are exhibited in response to heat shock After incubation at 37 °C for 50 min, the proteins induced in the heat-shocked cells comigrate with those induced by temperature shock of isolated salivary glands. The most prominent band again has a size of some 70,000 daltons.

A large shift in the polysome profile took place upon heat shock. At 25 °C, the polysome distribution shows a peak at 12–13 ribosomes per message; but after incubation at 37 °C for 10 min these polysomes disaggregate. After 30 min at the higher temperature, larger polysomes form, with 20–30 ribosomes on each messenger. At 50 min, this is the type of polysome observed on a gradient. Addition of actinomycin does not prevent the disaggregation but does inhibit appearance of the new (larger) peak, suggesting that these polysomes include the messengers newly synthesised in response to the heat shock. When the RNA from the heat-induced polysomes was isolated, it gave a single peak on a sucrose gradient, corresponding to a length of about 3,300 nucleotides. Presumably this peak includes several messenger species. This length of mRNA is sufficient to code for protein of up to some 120,000 daltons, and therefore can certainly be viewed as a possible messenger for the 70,000 dalton protein. When used for *in situ* hybridisation with salivary gland chromosomes, the RNA of the heat-shocked polysomes predominantly labelled band 87B of the third chromosome; however, in a note added in proof, McKenzie *et al.* conclude that this labelled material may in fact correspond to band 87C1. Bands 87A and 93D both also are labelled in this hybridisation, as is the chromocentre. The coincidence between the heavy synthesis of the 70,000 dalton protein and the heavy labelling of 87C1 lends support to the idea that this band may include the gene for this protein.

The identification of an individual band with a single protein, and the availability of the messenger RNA intermediate, in principle offer an opportunity to investigate in one instance the relationship between band and gene. Although genetic analysis suggests an equation between a band and a genetic function identifiable by mutation, which implies that only a small part of the band is used to code for mutationally visible protein, this does not formally exclude models postulating that other DNA in the band may code for proteins not identifiable by lethal mutations. The heat-shock system may offer a valuable independent opportunity to investigate the function of the band at the molecular level. If the functions of the proteins coded by the heat-shock puffs can be identified, this system also may allow the coordinate control of separated genetic functions to be studied since it comprises a small number of proteins whose synthesis readily can be switched on and off. And of course, it remains to be seen exactly how the expression of these functions enables the organism to withstand heat shock. □

Structure of a lectin

Crystallographic results

from C. C. F. Blake

ALTHOUGH the major effort in protein crystallography is at present centred on enzyme structure, structural studies on certain non-enzyme proteins may provide information of somewhat wider biological importance. One such group of proteins is the lectins. These molecules, found largely in plants, and particularly in seeds, have a number of interesting and unusual biological properties that derive from their ability to interact with cell surfaces. Their characteristic property is the ability to agglutinate erythrocytes, sometimes in a blood-group specific manner. Other cells may also be affected and most interestingly some lectins are preferentially able to agglutinate cells that have been transformed by viruses, carcinogens or radiation. In addition certain lectins are mitogenic; that is, they are able to stimulate the transformation of lymphocytes from small resting cells to large actively growing cells that may ultimately undergo mitotic division. The specific inhibition of the activity of many lectins by simple sugars has led to the conclusion that lectins bind specifically to saccharide chains on the surfaces of cells. The study of the structure and activity of these proteins could lead to an understanding of the molecular basis of their sugar specificity and the mechanism of their action on cells, which could in turn provide an insight into the structure and behaviour of the cells themselves.

Because of its availability and ease of extraction the most extensively studied lectin is concanavalin A from the jack bean. It is also one of the more interesting members of the group, because in addition to being haemagglutining, it is also mitogenic and capable of specifically agglutinating malignant cells. The concanavalin A molecule is composed of polypeptide chains that have a molecular weight of 25,500; below *p*H 6 the molecular species is a dimer, and above *p*H 6.5 it is a tetramer. The protein apparently binds to glucosyl and mannosyl residues at the non-reducing end of oligosaccharides, and it is most potently inhibited by α-methyl-D-manno- and glucopyranosides. Like other lectins concanavalin A requires the ordered binding of manganese and calcium ions before it can exhibit its sugar binding capacity.

Since concanavalin A was crystallised by J. B. Sumner as long ago as 1919, it is not surprising that it has more recently been the subject of extensive X-ray diffraction studies. The general features of the molecular structure were reported independently three years ago by Edelman's group at the Rockefeller University (Edelman *et al* , *Proc natn. Acad. Sci. U.S.A* , **69**, 2580; 1972) and by Hardman and Ainsworth (*Biochemistry,* **11**, 4910; 1972) at the Argonne National Laboratory. Recently a series of four papers has come from the Rockefeller group which reports the complete amino-acid sequence of the protein and a definitive description of its molecular structure (Wang *et al., J. biol. Chem* , **250**, 1490; 1975; Cunningham *et al* , *ibid* , **250**, 1503, 1975; Becker *et al., ibid.*, **250**, 1513, 1975, and Reeke *et al., ibid.*, **250**, 1525; 1975).

The X-ray studies have been carried out at 2.0 Å resolution on the tetrameric form of the protein with both types of metal ion bound The overall shape of the monomer is best described as a flat-based dome with dimensions of 42 Å×40 Å×39 Å. Its structure is dominated by two large, entirely antiparallel β sheets. One of these sheets, containing six strands, forms the entire base of the dome and is, unusually, almost lacking the twist normally seen in β sheets. The second β sheet, forming the central slice of the dome, lies at a shallow angle to the first sheet, with its seven strands twisted through 90°. The top of the dome is formed by a number of loops, mainly derived from the immediate N-terminal and C-terminal parts of the polypeptide chain. The quaternary structure of the protein involves two distinct types of subunit interaction, both largely involving the flat β sheet. Interactions of one type cause the monomers to associate in pairs with equivalent strands at the edge of the flat β sheet forming antiparallel hydrogen bonds, to give dimers that contain a 12-stranded β sheet. The second type of interaction involves the face-to-face opposition of these 12-stranded sheets from two dimers, contacts being made through both hydrophobic and ionic side chains that point outward from the sheets. Interestingly the domains of the immunoglobulins, to which the lectins have sometimes been compared, have a similar β-box structure and associate through interactions very like the dimer–dimer interactions in concanavalin A (for references see *Nature,* **253**, 158; 1975). But a more closely related protein is the thyroxine-binding plasma protein, prealbumin, which has both the same type of tertiary structure and subunit interactions (Blake *et al., J. molec. Biol.*, **88**, 1; 1974).

In each subunit the Mn^{2+} and Ca^{2+} ions are located in a surface cavity near the apex of the dome, only 4 6 Å apar

Carver (*J. biol Chem.*, **248,** 335

1973; *Can J. Biochem*, **53**, 371; 1975) applied these techniques to Con A they were surprised to observe large time-dependent changes in the water proton relaxation enhancement after Mn^{2+} was added to a solution of Con A.

Maximum enhancement was noted immediately after the addition and then the enhancement decayed to a reduced value with an apparent half life of ~20 minutes which strongly suggested that a slow conformational change was taking place. They were able to show subsequently that while the occupation of the transition metal binding site does not change the conformation of the demetallised protein, the addition of Ca^{2+} ions to the Con A–Mn^{2+} complex and of α-methyl-D-mannosides to the Con A–Mn^{2+}–Ca^{2+} complex perturbs the protein structure.

Grimaldi and Sykes (*J. biol. Chem.*, **250**, 1618; 1975) have recently developed an elegant stopped-flow NMR method which allows them to follow the kinetics of the various conformational changes induced in Con A by the ordered binding of Mn^{2+}, Ca^{2+} and α-methyl-D-mannoside from measurements of the time-dependence of the water relaxation enhancement under controlled conditions. The sensitivity limitations of the NMR technique often militate against successful kinetic applications but in this case where the intensity of the large water signal is being followed this is not a problem. An advantage of using NMR for such studies is that the NMR parameters for the species involved in the kinetic process contain information about molecular parameters such as number of ligand sites, ligand exchange rates and correlation times for the interaction.

Three separate conformational states of the protein could be discerned in the kinetic experiments and it was possible for Grimaldi and Sykes to outline the order of the steps in the binding process For example, the conformational changes induced by adding Ca^{2+} to Con A in the presence of Mn^{2+} resulted in intensity changes of the water resonance which could be analysed according to first-order kinetics. From the dependence of the observed rate costants on the Ca^{2+} concentration it was deduced that the Ca^{2+} binds rapidly to the Con A–Mn^{2+} complex producing a decrease in relaxation enhancement and this is followed by a subsequent conformation change giving a further decrease in enhancement. The decrease in enhancement probably results from a restricted rate of access of the water molecules to the bound Mn^{2+} following the large conformational change When Ca^{2+} dissociates from the conformationally changed protein the water proton relaxation enhancement remains constant, indicating that the protein retains its conformation.

Grimaldi and Sykes have also examined the kinetics of binding the sugar α-methyl-D-glucoside to Con A in the presence of Mn^{2+} and Ca^{2+}. It should be mentioned that there has been some controversy concerning the sugar binding site in Con A. Measurements of the paramagnetic contribution to relaxation rates of carbon-13 nuclei in α- and β-methyl D-glucopyranosides bound to Con A (Brewer and coworkers, *Biochemistry*, **12**, 9448; 1973) indicate that the sugars are much closer to the manganese ion (mean distance ~10 Å) than was suggested by earlier X-ray diffraction studies (20 Å).

In the kinetic studies of Grimaldi and Sykes the initial binding of sugar was considered to be at a site well removed from the metal binding sites and it does not influence the water signal. There is, however, a subsequent slow conformational change after the sugar binding which increases the water proton relaxation enhancement. This is followed by a further slow conformational change which is essentially the same as that resulting from Ca^{2+} binding in the absence of sugars.

3 . . . 2 . . . 1 . . . 0?

from C H. L. Goodman

ONE-DIMENSIONAL conductors are suddenly the fashionable field of solid state research, and a flood of short but weighty notes in *Physical Review Letters* and *Solid State Communications* warns of massive presentations and theses in the pipeline. It also heralds organic compounds with conductivities like those of metals, and even a completely new type of superconductor.[1]

Electrical conductors normally encountered are relatively isotropic, conducting to a more or less similar extent along any of their three dimensions. Perhaps the only reasonably common material showing pronounced anisotropy is graphite, which in well crystallised material, has an electrical conductivity within the two dimensions of its hexagonal sheets 10^4 greater than perpendicular to them. Such 'layer lattices' have been the subject of a great deal of research over the past ten years. Fairly recently however there has been a sharp switch of attention to 'one-dimensional materials' (composed of parallel long chain molecules).

There are three main materials being studied at present: TTF : TCNQ (tetrathiafulvalene: tetracyanoquinodimethane), the polymer of sulphur nitride (SN)$_x$, and KCP (K$_2$Pt(CN)$_4$ Br$_{0.3}$ 3H$_2$O). All show high electrical conductivity along the chain axis, and rather small conductivity perpendicular to it. They look metallic to the eye, but as might be expected show marked optical anisotropy with polarised light.

Until recently the most dramatic research has been associated with TTF : TCNQ. Heeger and his group at the University of Pennsylvania believed they had discovered a possible organic high temperature superconductor[2] — certainly with a room temperature conductivity of 10^3 (ohm cm)$^{-1}$ rising to nearly 10^5 (ohm cm)$^{-1}$ just below 60 K, this material is a most highly conducting solid and has been much investigated[3]. The sharp transition to a much more resistive semiconductor at 58 K was interpreted as resulting from a Peierls instability — a type of crystallographic distortion which is expected in these materials[4] but which might be avoidable by disordering the material in some way or by modifying the structure. Thus IBM workers have recently reported[5] the transition being reduced to 40 K with the selenium analogue, TSeF : TCNQ.

The platinocyanide, KCP, also shows high electrical conductivity rising sharply as temperature is reduced, but this material (and its chloride analogue) again undergoes a transition to a high resistivity solid. Its study has been bedevilled by its chemical instability: the water molecules which stabilise the structure can get lost well below 100 °C, and in any case the correct structure has only recently been established[6,7].

Probably least understood is (SN)$_x$; it is one-dimensional[8], though with helical rather than linear chains; it is metallic and conducts well even at low temperatures[9]. But what has particularly excited interest is that it has recently been found to be a superconductor[1], albeit with a very low transition temperature (0.26 K), the first quasi one-dimensional superconductor to be discovered. It is interesting that the discoverers refer to the weak inter-chain coupling as a possibly important factor

The key to all these one-dimensional materials in fact almost certainly lies with what are usually termed the van der Waals bonds holding the chains together in the crystals. These bonds are not too well understood and some degree of electron orbital overlap may be involved. It is probable however that crystal growth presents a related but more immediate problem, perhaps a real practical barrier to progress. One cannot but be suspicious that 'one-dimensional' crystals appear to be capable of being 'fattened up' during growth, whereas a truly one-dimensional crystal should not be able to nucleate on its sides and should persist in (linear) growth with the diameter of the seed (assuming that the latter can be obtained). To me the observed 'growing-out' means either that structural imperfections are present due to forced growth or (and it may amount to the same thing) that chain branching can somehow be induced during growth. If this view is correct the most perfect one-dimensional crystals will be those which are most acicular, not the more equiaxed shapes which have been prepared, after much effort, to give large area specimens for physical measurement.

Finally if van der Waals bonds are so important should not someone be looking at zero-dimensional crystals — those held together only by van der Waals forces (or at least what are usually thought of as them)? These crystals by definition would not be metallic, of course, unless 'intercalated' (if that were possible) but their transport properties could be interesting. If a suggestion is in order, GeI_4 and SnI_4 with their brilliant vermilion-red hue do have a most attractive appearance!

Science and religion

from a Correspondent

For the past three years there have been a number of informal consultations between scientists who have been concerned to relate their scientific knowledge and modes of study to their religious faith and practice. Those involved decided in 1974 that their deliberations should be more widely known and from April 10 to 12, the 'Science and Religion Forum' was inaugurated, at a meeting at van Mildert College, Durham, devoted to 'The Problem of Consciousness'.

THE problem was introduced by a paper on "reductionism in biology" by A. R. Peacocke (University of Cambridge), who distinguished between different forms (ontological, methodological and epistemological-linguistic) of 'reductionism'—roughly, the analysis and explanation of entities in terms of their component units, for example explaining all biology in terms of physics and chemistry. Some forms of reductionism would be generally agreed as simply required methodologically by scientific research, but others represent a more general position which can determine attitudes to the relation between consciousness and brain states. Mary Hesse (University of Cambridge), expanded this discussion by describing certain non-additive, non-reducible situations in the quantum physics of particles. Higher-order relations can emerge in complex (for example living) systems which, not in any mysterious metaphysical sense, constitute a kind of logical irreducibility. For example, the analogy of programming from computer science could be valuable in providing a non-reductive valid way of talking about consciousness.

T. Appleton, of the University of Cambridge, gave an account of studies on communication and language at various levels in the biological world and, in particular, described recent work on primates, which shows evidence of a higher level of consciousness, based on their ability to communicate through American Sign Language, than previously thought from studies of verbal communicating abilities.

Howard Robinson, of Liverpool University, outlined, for the benefit of a predominantly scientific audience, the state of the mind–body problem in contemporary philosophy which has concerned attempts to make materialism philosophically respectable—attempts which though widely canvassed, have made only a limited number of converts and which Mr Robinson rejected. Some form of materialism was, in fact, that adopted by a number of those who joined in a general discussion session which inevitably focused on the sensitive area of concepts such as 'soul', 'immortality' and 'personal identity' in relation to scientific, philosophical and theological ideas.

Professor John Bowker (University of Lancaster) described the development of religious consciousness in terms drawn from systems analysis and information process. He drew attention to the extent to which religions function as bounded systems of information process, in which resources are made available to human beings for the construction of a life-way from birth to death—and traditionally in religions, through death as well. 'Religion' and 'science' were originally undifferentiated, emerging from the general endeavour of men to defend and maintain the continuity of their life-way in relation to the limitations which circumscribe it. The sense of God is effective and dynamic as an informational resource in the construction of human life : to take an example, it would thus be possible to interpret Jesus as the totally God-informed person retrieving in the scan of every situation the cues through which the 'sense of God' is stored in human brain-behaviour, and thus himself becoming a resource for the construction of a religiously-informed human being

At very short notice, the Bishop of Durham, John Habgood, spoke on "religion-and-science and the church". He stressed the need for philosophical sophistication in the science–religion debate; for reconciliation between the idea of continuity assumed by scientists and that of discontinuity implicit in the beliefs of ordinary Christians; and for man's responsibility for nature (including the ethics of research) to be a principal concern of those present.

Two-step transfer reactions between heavy ions

from P. E. Hodgson

LAST year some measurements were made of the differential cross section of the ^{48}Ca(^{16}O, ^{15}C)^{49}Ti reaction at 56 MeV by the Argonne group (Kovar *et al.*, *Phys. Rev. Lett.*, **33**, 1611; 1974). This is a strange reaction: at first glance it looks like a one-nucleon transfer reaction, but closer examination shows that the transferred 'nucleon' must carry two charges. The only possible mechanism is thus a series of nucleon transfer reactions equivalent to a transfer of two protons minus one neutron. This might be expected to be very unlikely, but in fact it is found that the cross section of the reaction to the ground state of ^{49}Ti is comparable to that of normal one-nucleon transfer reactions.

In recent years there has been much interest in multistep contributions to nuclear reactions. These are recognised to be of two types: first those that can proceed through the excitation of the target or the residual nucleus by inelastic scattering (*Nature*, **251**, 188; 1974) and second those proceeding by a series of particle transfer processes. Calculations have been made in a variety of ways for both processes, and in many cases it has been found that the inclusion of multistep contributions greatly improves the agreement between theory and experiment.

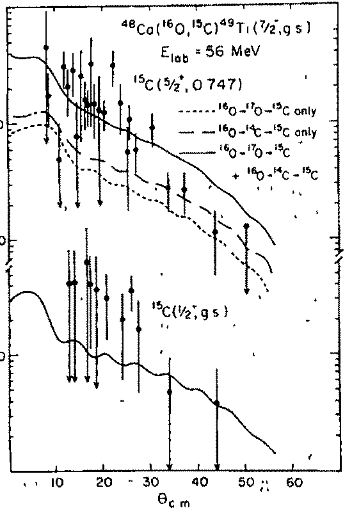
In most of the reactions studied so far both these processes could conceivably contribute, and it is sometimes not clear which is the dominant one, except in reactions involving highly collective nuclei which are very easily excited by inelastic scattering, so that the first process dominates. The special feature of the (^{16}O, ^{15}C) reaction is that it must proceed by successive particle transfer, and so it furnishes an excellent case to test the multiple particle transfer theories.

These calculations are exceptionally complicated because in heavy ion reactions it is not sufficiently accurate to make the zero-range and no-recoil approximations that greatly simplify the calculations for light ion reactions.

The Texas group of Tamura, Udagawa and Low have however found ways of carrying out the full calculation for heavy ions without loss of accuracy and sufficiently economically for them to be done in a practicable time on a fast computer. They have written computer programs to do both types of multistep calculation for heavy ions, and have now applied one of them to the ^{48}Ca(^{16}O, ^{15}C)^{49}Ti reaction (*Phys. Rev. Lett.*, **34**, 30; 1975).

They considered two possible reaction mechanisms, one-neutron pickup followed by two-proton transfer and *vice versa,* and added their amplitudes to obtain the total cross section. Written out in full, the two reaction mechanisms are ^{48}Ca(^{16}O, ^{17}O)^{47}Ca(^{17}O, ^{15}C)^{49}Ti and ^{48}Ca(^{16}O, ^{14}C)^{50}Ti(^{14}C, ^{15}C)^{49}Ti. The intermediate nuclei ^{47}Ca and ^{50}Ti were assumed to be in their ground states and in the first reaction the ^{17}O nucleus could be either in its $5/2^+$ ground state or its first $1/2^+$ excited state, leading respectively to the $1/2^+$ ground state and $5/2^+$ excited state at 0.747 MeV in the final nucleus ^{49}Ti, both of which were observed. In the second reaction the ^{14}C nucleus remained in its ground state.

As the experimental cross sections are structureless and of low accuracy it is not possible to make a good test of the calculations solely by the fit to the angular distribution. It is necessary to try to reproduce the absolute magnitude of the cross section, and this is particularly important because one of the exceptional features of this reaction is the high value of the cross section to the ground state of ^{49}Ti.



Differential cross section for the ^{48}Ca(^{16}O, ^{15}C)^{49}Ti reaction to the ground and first excited states of ^{49}Ti compared with exact coupled reaction channel calculations. The contributions of the two postulated reaction mechanisms are shown separately and added together.

To obtain an absolute cross section all the parameters of the calculation must be fixed beforehand by reference to other reactions. This was done in the present case by fitting available data for the one-neutron transfer reaction ^{48}Ca(^{16}O, ^{17}O)^{47}Ca and the two-proton transfer reaction ^{48}Ca(^{16}O, ^{14}C)^{50}Ti which are the same or similar to those involved in the postulated mechanisms for the ^{48}Ca(^{16}O, ^{15}C)^{49}Ti reaction.

The results of these calculations are shown in the figure, and it is apparent that the absolute magnitudes are correctly given, and that the shapes of the calculated angular distributions are consistent with the experimental results. It is particularly gratifying to find that the relatively high cross section of the reaction to the ground state of ^{49}Ti is correctly given. The relative magnitudes of the two reactions are attributable to complicated interferences between the contributing processes.

More precise data are needed before we can learn more about the details of this reaction, and other possible contributing processes must be considered, but this pioneer calculation of a multistep particle transfer process shows that these reactions are now amenable to quantitative calculations, and it is likely that many more such calculations will be made in the future.

Engine with a solid working fluid

from Robert W. Cahn

THE faintly surrealistic title of this reportage denotes a faintly surrealistic concept. All 'heat engines' hitherto have been designed to operate with working fluids: the fluid may be steam, petrol vapour/air mixture or air (in the Stirling engine), but all depend on cycles involving simultaneous changes of temperature and pressure. Now it is proposed to design an engine in which changes of temperature and stress are applied to a metallic spring, which constitutes the working 'fluid'.

The idea (which is not altogether new) is revived in a paper by Tong and Wayman (*Metallurgical Transactions,* **6A**, 29; 1975). The spring has to be made of one of the alloys—a select band—which exhibit shape-memory. The peculiar properties of these alloys have featured in these pages before (*Nature,* **219**, 895; 1968; **224**, 844; 1969). Essentially, such an alloy can be 'imprinted' with a suitable shape, such as that of a spiral spring, by plastic working followed by heat treatment. It can then be pseudo-plastically deformed at or near ambient temperature: it will retain the new shape until it is heated to a higher temperature (typically 100 °C) and it will then return to its imprinted shape, even against a substantial restraining force seeking to prevent it. It can then be cooled back to ambient temperature without further distortion. Tong and Wayman point out that this sequence can form the basis of a heat engine to utilise solar heat or waste heat. They do not consider the engineering design (though they refer to a properly engineered prototype recently constructed at the Lawrence Radiation Laboratory) but they do attempt to evaluate the ideal cycle efficiency of such an engine as a function of various metallurgical variables, and conclude that an ideal efficiency of about 20% should be quite feasible.

Part of the charm of the idea is that the critical temperatures of the alloy, which define the upper and lower temperature limits of the cycle, can be varied within wide limits, both by going to different alloy systems and by small changes of composition within one system. Nearly equiatomic Ti/Ni alloy (Nitinol) is probably the most promising—and most thoroughly investigated—material; it has a virtually unlimited tolerance of mechanical cycles without fatigue.

The engineering aspects of a solid-state engine will require a good deal of design ingenuity Ideally, it would seem, a simple engine should incorporate two or more springs (or other more elaborate configurations), so that one could be heated up while the other gives up its heat to a sink; heat transfer during both heating and cooling would need to be rapid if the engine is to be anything more than a mechanical tortoise. Presumably a heat pipe to earth would be necessary. An engine of this type might, for instance, be designed to pump irrigation water in deserts, using solar energy.

Shape memory is merely one of four closely linked metallurgical phenomena: thermoelastic martensitic transformations (progressive, thermally reversible shear transformation); pseudoelastic behaviour (large strains, much larger than normal elastic strains, brought about by shear transformations that are themselves reversible with stress); shape memory effect; and a two-way shape memory effect, which involves shape changes induced by temperature changes alone, without intervention of stress. Some alloys show most of these, some show only one; some show an effect in single crystal form, others will do so in the normal, polycrystalline form. The tangled connections between the various effects have been clearly analysed in an important series of papers by Delaey, Krishnan, Tas and Warlimont (*J. mater. Sci.*, **9**, 1521, 1536, 1545; 1974): the authors list all the alloys that have been found to evince any of these effects and analyse the structural, mechanical and thermodynamic features that underly them. These papers are essential reading for anyone who would like to have a go at a solid-state engine. Delaey and his colleagues have provided the steam tables, as it were, of the solid-state engine

Tong and Wayman have recently published another paper (*Acta Met*, **23**, 209; 1975) in which they analyse some of the thermodynamic variables that predispose an alloy to thermoelastic or shape memory behaviour. One interesting conclusion, which is given an interpretation in terms of the 'quasi-chemical' bond-energy approach, is that an ordered alloy (such as Fe_3Pt) has a lower latent heat of transformation, and is more easily able to undergo thermoelastic transformation, than the same alloy in an ordered form. This seems to be a generally valid conclusion.

The solid-state engine may well be able to compete with other physical devices, with or without radiation concentrators, for extracting power from solar radiation. According to Brinkworth (Solar Energy for Man, Compton Press, 1972) such devices have ideal efficiencies in the range ½-1% (for simple thermoelectric generators) to as much as 30% for thermionic generators with concentrators. The latter are likely to be even more expensive on capital than a solid-state engine, and do not directly generate motion. The engine would seem to deserve some further investigation, which will certainly require the collaboration of metallurgists and mechanical engineers.

Successful quake prediction made

from Peter J. Smith

THERE is now ample evidence that some small to moderate earthquakes are immediately preceded by a period during which the seismic velocity ratio (V_P/V_S) in the vicinity is anomalously low. This effect was first observed by Kondratenko and Nersesov (*Tr. Inst. Fiz. Zemli Akad Nauk SSR*, **25**, 130; 1962) in the Garm region of the USSR for events in the magnitude range 4–5; but similar V_P/V_S changes have since been detected in respect of magnitude 2–3.3 earthquakes at Blue Mountain Lake (New York State), the magnitude 6.4 San Fernando earthquake of 1971, the magnitude 5 Bear Valley (California) earthquake of 1972, two shallow earthquakes in Japan and several other events in various parts of the world. The importance of this phenomenon lies in its potential for earthquake prediction, the more especially as the duration of the precursory V_P/V_S anomaly seems to be related to shock magnitude. But can the potential be converted to practice? In each of the examples cited above, the precursory behaviour was detected by data analysis subsequent to the event. Aggarwal *et al* (*J. geophys. Res*, **80**, 718; 1975), however, are now able to report that they have made a genuine and successful prediction.

It was Aggarwal and his colleagues who caried out the original study of the 1971 earthquakes at Blue Mountain Lake, thus becoming the first (*Nature*, **241**, 101; 1973) to confirm the Soviet observations of ten years before. The larger events in the 1971 series were preceded by V_P decreases of 15–20% and V_S decreases of 5–10%. Subsequently, however, the region became relatively quiet seismically until on 14–15 July 1973 the calm was shattered by two magnitude 3.6 and four rather smaller earthquakes. In response to this renewed activity, Aggarwal *et al.* immediately (15–16 July) set up a system of portable seismographs and strong motion accelerographs to supplement (for six weeks) the permanent BML station.

During the first third of this period, the recording system indicated an average S wave–P wave travel time ratio (t_S/t_P) of 1.73 Over the few days following 30 July, however, t_S/t_P decreased to about 1.5. In 1971 the corresponding 'normal' value of t_S/t_P had been about 1.75 and reductions comparable to that now observed had preceded by several days' earthquakes of magnitude 2 5–3.3. Aggarwal and his colleagues thus took the t_S/t_P decrease of 31 July–2 August 1973 to herald a shock of comparable magnitude. On the night of 1 August they therefore predicted that an earthquake of magnitude 2.5–3.0 would occur within a few days.

The maximum magnitude of the apparently impending event was estimated from the inferred spatial extent of the t_S/t_P anomaly In contrast with the situation in 1971, the most distant (common) station in 1973 remained unaffected and thus presumably lay outside the anomalous zone. Assuming the size of the anomalous region to be directly proportional to the magnitude of the responsible event, and comparing the 1973 data with those of 1971, the upper magnitude limit of the expected earthquake was about 3. The minimum magnitude was obtained by estimating the minimum duration of the t_S/t_P anomaly. The 1971 results had showed that, following its initial rapid decrease, t_S/t_P had returned to its normal value rather more slowly and had reached it about one day before the earthquake occurred. As by 1 August 1973 t_S/t_P showed no sign of increasing, precedent suggested that the expected earthquake was unlikely to occur for at least two days, making a total t_S/t_P anomaly time of at least four days. And according to the previously established magnitude–precursor time relationship (Scholz *et al.*, *Science*, **181**, 803; 1973), this would correspond to a magnitude of 2.5.

The earthquake which occurred close to the edge of Blue Mountain Lake on 3 August 1973 had in fact a magnitude of 2.6. Aggarwal and his colleagues are thus the first to predict successfully the place, time and size of an earthquake in the United States and the first to make practical use of precursory seismic velocity changes. Moreover, in their method the precursory interval (whose onset may be detected but whose duration cannot be known until t_S/t_P returns to normal just before the impending event, which may be too late) may be used for predictive purposes before it is complete. If, as seems likely, the size of the anomalous region associated with an impending earthquake is a unique function of the shock magnitude, it follows that once the anomaly appears (and assuming it grows rapidly to its full extent) its spatial dimensions should give magnitude directly. The magnitude can then be fed into the known magnitude–precursor time relationship to determine how long the anomaly will persist and thus just when the earthquake will occur. In short, in any particular case prediction may not have to await the gradual approach of t_S/t_P towards its normal value; valuable time may be gained by making the critical measurements before the rise in t_S/t_P even begins.

Obviously, for this method to succeed it is essential that the size of the anomalous zone be measured reasonably accurately; and here there are difficulties. For one thing, the size of the zone may vary with time, which would complicate the supposed relationship between zone size and magnitude. The temporal characteristics of this relationship are not yet known, although there is evidence that if the anomalous zone grows it must grow relatively rapidly. Second, it would clearly be advantageous to use explosive sources to determine precursory velocity changes and thus define the extent of the anomalous region But in this case care must be taken to ensure that the waves actually penetrate the zone of anomaly. Aggarwal *et al.* show that large changes in V_P and V_S are not observed at shallow depths (less than 0.5 km at BML) for near-horizontal wave paths. This could mean either that significant velocity anomalies do not exist at these depths or that the cracks there are predominantly horizontal. Either way, some sort of anisotropy is implied; and this is likely to complicate the mechanics of the prediction method.

Manpower supplement

In this issue we put together a number of articles on different facets of scientific manpower. This can in no way be regarded as a comprehensive survey; rather we have considered a number of subjects and of countries and have taken one person's view in each case. The treatment is very largely journalistic—if that means that our analyses lack the background of years of experience it also means that they lack much self-congratulation and a sense that all is necessarily for the best. For in some ways the purpose of this supplement is to warn that the question of the use of scientific manpower is increasingly not one which can be ignored. It is becoming abundantly clear that the system by which schools supply universities and polytechnics which supply schools, industry, government and themselves is not automatically self-regulating.

At the heart of manpower issues are several contradictions:

- Scientists or their representatives are increasingly looking for life-long tenure, although science itself proceeds more by revolutions and perpetual rejuvenation.
- The waning appeal of science to the young is widely believed to be largely because science is highly specialised and dissociated from human dimensions and therefore unattractive, but this is just at a time when some of the questions that are being asked of science are simple, stimulating, strongly related to human needs, and highly multidisciplinary.
- Bad news about employment prospects can affect the choice of career of a prospective scientist six or more years before employment prospects become relevant.
- At a time when the techniques of manpower planning are being criticised for coming up with the wrong answers, the British Department of Education and Science apparently intends to use the manpower-planning approach in formulating some of its policies for higher education.
- Academic life is supported in great part by the taxpayer and yet intervention by government in university affairs is all but unthinkable.
- Scientists, particularly in government and industry, often experience a conflict of loyalties between their employer and the wider, often international, cause of science.
- Students, for various reasons, can occasionally get hooked in large numbers on subjects such as astronomy in which employment prospects are poor and universities often powerless to do much except absorb all-comers.

Perhaps one of the most tricky problems of manpower use is the all-growing-old-together syndrome. This can be seen around the world in two totally different situations—defence establishments and new universities. In the 1940s, in response to the demonstrable success of scientists in the Second World War and the emergence of the Cold War, many new establishments were formed and many old ones recruited in large numbers. Likewise in the 1960s in Britain (and later in some other parts of the world) many new universities were built and absorbed vast numbers of young researchers as teaching staff. The degree of homogeneity in both these groups is undoubtedly higher than elsewhere, but homogeneity coupled with a growing seniority is not necessarily the best of environments for research. And recruitment within a narrow temporal band often means that people are taken on simply because they are around rather than because of any intrinsic merit they possess.

There are many other topics worth pursuing—brain drains, the PhD in industry, retraining programmes, the research scientist as school teacher, are but a few. The only things that can be said with much certainty about the scientific profession at present are that a young man entering at 21 can not expect an uninterrupted ride to 60, and that the scientific community is going to hear more and not less of the word manpower in the next few years.

Excess demand in the graduate employment cycle

John Hall

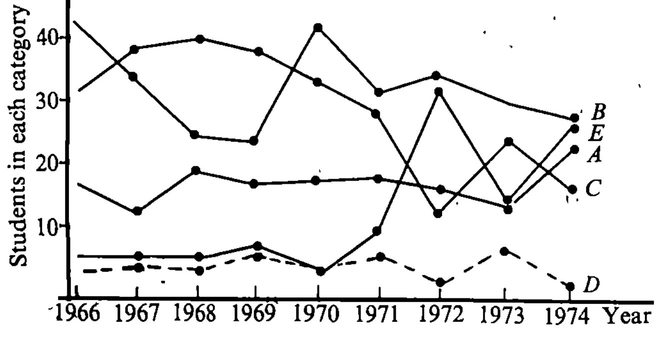
After the lean years of the early 1970s the traditional employment of science graduates is picking up, but the result is likely to be a shortage because the graduates have found that non-traditional jobs can be quite attractive.

THREE years ago, anyone embarking on an account of how scientific manpower problems were affecting British university science departments would have had a field day. The big twelve companies who normally take most of the country's new science graduates had developed cold feet because of an acute economic recession, and the last people they needed on their payrolls were recently qualified specialists who knew next to nothing about industry and would take at least two years to start paying their way. Some companies pared their intake dramatically, others simply said they would take no chemists, or chemical engineers or metallurgists at any price. Alarming noises about the growing pool of unwanted science graduates were to be heard from universities like Manchester, and nobody dissented too vigorously from the view that there would never again be a return to demand of the mid-1960s for chemistry graduates.

Up and down the country, careers masters read their newspapers and sixth formers listened to hard-luck stories from 'old boys' who were selling vacuum cleaners door-to-door because there were no more laboratory jobs available and, shortly, entrants were avoiding the worst-affected courses in such numbers that chemistry professors began to look nervously over their shoulders in case anyone noticed that there were not all that many people to lecture to any more. (The staff–student ratio was a nonsense in an area which had an important research function, they implied, and in any case, as one professor pointed out in a letter to *The Times*, the laboratory assistants on the payroll made the picture look bleaker than it really was.)

Now it is the turn of the science-based industries to sweat things out, and university chemistry and chemical engineering departments are in the position of supplying an increasingly scarce product in a seller's market. The better graduates are being offered a choice of up to six jobs this year, and in 1974 chemical engineering graduates at the University of Manchester Institute of Science and Technology (UMIST) were accepting first appointments at around £3,000 a year. One started at £5,000. The only people who seem surprised by the turnaround are the unfortunate recruiting officers who closed industry's doors so recently and announced that the golden days were over. Now they have the doors open again, and they are explaining that they had never meant that they should be taken so literally when they said what they did. But nobody (in the universities at least) is shedding too many tears over industry's plight, because there is a fairly unanimous opinion that the wound was self-inflicted. What is more, many departmental heads and appointments board people went to great pains in 1971 and 1972 to point out to bashful employers the likely effects of over-reacting, and now those effects are to be observed, precisely as predicted, they can be excused a little self-congratulation.

Fig. 1 First destinations of graduates of the University of Manchester. *A*, Teacher training; *B*, postgraduate work; *C*, chemical or allied work; *D*, 'still looking' six months after graduation; *E*, commercial or other work.



In hard times, the universities said, industry would clearly be making some cuts in its recruitment programmes. If those cuts were reasoned and moderate, there would be a corresponding feedback to the schools, where there would be a gradual and appropriate decrease in the number setting out to be chemists (or whatever). According to this picture, industry's decreasing demand and the universities' decreasing supply of scientists would describe similar trajectories on a graph of the affair, levelling off to run in parallel towards an infinitely distant point of mutual satisfaction.

An alternative approach was for industry to base its recruitment plan on that year's trading figures, without reference to much else. In this situation you cry out for all the manpower you can lay hands on when business is going well, and when the books begin to look bleak you reduce recruitment drastically, or if it is a really bad year you cut it out, period. Now, the news gets back to the schools that there is simply no way in which anybody is going to make a living as (say) an industrial chemist. The vacuum cleaner salesman confirms what the careers master has read and, instead of getting a tapering off of supply, the universities find that the bottom drops out of the market in the appropriate subject. This would be an admirable approach if it took twelve months to train a chemist from his entry into the lower sixth form at school. As it happens, it takes five years for subject options made at school to be translated into terms of graduate supply, so if industry were to take this line then it would be fairly crucial that it be absolutely certain of its manpower requirements five years ahead.

In the event, science-based industries proved to be no better than anyone else at forecasting needs five years in advance, and as a result it is now in the market for people whose scarcity is a direct result of its own short-term manpower policies. Because of the time lag between the industry's statement of its manpower requirements (or non-requirements) and the effect of that declaration on graduate output, the graph shows two curves in constant oscillation about an axis which they both cross about once in five years. Industry pays through the nose when the scientists' supply curve is at its nadir, and the demand curve peaks. When it happens the other way round, the scientists pay for it.

Responses

As university students and teachers are thinking beings, and not the mute commodities which the supply and demand equation supposes, however, they are able to make adaptations to reduce their vulnerability, and since they received their last fright from industry about four years ago there have been at least two changes which strengthen their position. Industry's recruitment cut-back made many science-trained graduates look for jobs in areas which were, traditionally, beyond both their area of interest and their grasp. They moved, often out of sheer desperation, to the professions which offered a kind of institutionalised security and which had been historically the preserve of the arts graduate—that is, to the Inland Revenue, to insurance, business management, accountancy, and even law. These new directions, although often taken as makeshifts, have been found by science graduates to be surprisingly pleasant alternatives to the accepted routes through the research and development or academic career structures—so much so that although the necessity for science graduates to seek non-traditional alternatives as their first-destination employment has now been largely removed, there has not been a corresponding switch back to the traditional jobs. In effect, it has been established that a scientific education may be regarded as a non-vocational training for a variety of non-scientific careers.

Table 1 Possible employment of new chemical engineering graduates in 1978

Public service and education			25
Public Service			
Civil Service, local authority, river boards, and H.M. forces	20		
Education

Total entering permanent employment in this country			470
Employed overseas (on permanent or short term basis)			40
Returning home overseas or otherwise not available for employment			40
Failing to keep in touch or taking more than 6 months to find permanent employment (as in recent surveys)			100
Higher education and training (including teacher training)			180
Total output of graduates required			830
This total is based on a distribution of home to overseas students of 730 home to 100 overseas			
1975 intake to university chemical engineering departments required to provide this output		950	

The Institution of Chemical Engineers, which is keen to see a restoration of equilibrium in the demand and supply of new graduates, conducted an investigation leading to an estimate of the demand for graduate chemical engineers in 1978 (published in *Chemical Engineer*, March, 1975). A report presented to the institution's Careers Committee was prepared, by way of a preliminary estimate, by combining first-employment surveys and assessments by industry and Institution members. The resulting Table above is believed to be a conservative estimate of the possible destination of new graduates and shows that the universities should be producing about 830 new graduates each year. Allowing for the usual wastage rate, the intake to universities should be in the order of 950. The actual intake could be as much as 400 short of this target.

This response to a scientific manpower surplus was foreseen as long ago as 1961, when a government report (*The Long Term Demand for Scientific Manpower*) welcomed the possibility of scientists moving into non-scientific careers. A surplus of scientists over immediate demand for employment, said the report, "should make possible a rational, as opposed to an emergency use of scientific disciplines. It should mean that at long last we shall have a supply of qualified manpower with a scientific training for management, administration and the professions generally, in addition to those who up to the present have been drawn inevitably into vocational employment. We do not doubt that scientific education will adjust itself to this new prospect; and that in the same way as only a proportion of those trained in the classics and history have expected to find employment in their own fields of study, an increasing proportion of those trained in specialised scientific disciplines will obtain employment outside them. We think that both science and the nation will benefit from this adjustment."

What the student employment applications for 1974 and this year show is that the trend foreseen in the 1961 report as a response to a manpower surplus situation is continuing at a time when the conditions which gave rise to it have subsided. A second change which has occurred as a result of the falling demand for scientists at the beginning of the decade is that course content has changed (and in some cases entry requirements) in order to secure students with a broader initial outlook and a broader and more flexible operational capability on graduation. The notion that it is possible to predict when a student enters, the market forces which will prevail when he leaves university has in many places been abandoned; the aim is rather to give the student a hard core of indispensible knowledge in his special area, and to offer a range of options which will make him sufficiently versatile to take advantage of such employment opportunities as present themselves, whatever they may be.

Trends

Apart from making the science graduate a more adaptable individual than he was formerly, the cut-back in demand has also tended to make him think in a very positive way about the direction he wishes his career to take. Whereas during the 1960s anyone going to university to read chemistry accepted without much thought about the matter that he would work as a chemist in industry, in government research or in a university, that assumption is no longer made today. Appointments board officers at Cambridge, Manchester and Imperial College, London agree that the changed circumstances of the science graduate in the early 1970s have produced a situation in which the student has become accustomed to making an active decision about the way his working life will start. They also agree that, although this may be bad news for ICI, or Shell, or for the government centres which automatically expected a visit from the best students every year, it is good news in an educational (or existentialist) sense that people are exercising a more conscious choice about their personal destinies.

On the same level, there is also a feeling that student intake to science has not taken such an upward turn as employment vacancies because of a positive decision among school leavers that science is directly responsible for many of society's ills, and that they will not be a party to any extension of the technological nightmares which beset the Western world. The universities tend to point out, without any sense of historical conviction, that scientists are the only people who are ever likely to make the bad dreams go away, which is rather like saying that peace can only be enforced by the military. And they try to court the science-shy with courses on environmental studies, pollution control and energy sources—which is progress, of a kind.

What universities think

Specific information about science students, courses and employment trends at Manchester, Cambridge and Imperial College can be summed up as follows:

- **Cambridge.** Science courses are generalised until the third year, when a specialist option is taken. The number taking chemistry is so small that professors are starting to worry about the security of their salaries and employers are falling over themselves to get at the few who emerge with chemistry degrees. In the past, the pressure has been on people who are doing fairly well at their subjects to pursue them to the bitter end; that is, to take their higher degrees and go into academic work. But this year it is noticeable that the academic world is not proving as attractive, which is hardly surprising when final-year students looking for openings in university teaching see nothing more rosy than appointments on a one-year tenure. (Professor A. B. Pippard is reported to have said that there is no future in the universities for 90% of the science students who are there now, and that looks like an optimistic estimate.) The consequences of the last cut-back are to be seen in student career choices (accountancy, business and so on) and in the attitude of employers from these areas, who are prepared to regard science as a general training in thinking and, therefore, as an acceptable entry qualification for a variety of non-scientific jobs. Buoyant areas are electronics and communications. General prognosis for the science subjects: an upturn in intake and in employment opportunities, but never a return to the levels of the 1960s.
- **Imperial College, London,** prides itself on having a finger on the pulse of industry, and for this reason claims that it never had any real problem placing its graduates although there was a distinct drop in the number of applicants for chemistry courses last year. Maybe it never had much trouble in its placings because it has a tradition of sending people to a wide range of careers (up to 20% make for areas like banking and insurance). They report that since people tried teaching as a life-raft during the lean years it has become a popular career choice on its own merits. The demand for chemists and chemical engineers is well up, and Imperial College says it did not really notice a serious decline in the demand for chemists at any stage. (In the 1970–72 period when the national unemployment figure stood at 16%, Imperial College's graduate unemployment was less than 0.5%.) In its best years, the chemistry department had up to 1,000 applicants for 95 places. This fell in 1974 to 220-odd applicants for 60 places, but this year applications are up 30% on last year. Imperial College sells its graduates by emphasising project work, individual initiative in problem solving, and practical laboratory experience. It also makes a good showing on integrated studies like the history and philosophy of science and languages.
- **Manchester.** The university hopes the decline in chemistry applications has bottomed out and is on the increase again. This year there are 60 final-year chemists, compared with 80 to 95 in the best years. There is a demand for Manchester's chemists, who now do a course of two years' hard-core chemistry, followed by a year of options which include environmental chemistry, psychology, management and liberal studies. Flexibility is the keynote. The metallurgy department, with less than half the number of students it had in 1972 (and with the national total of metallurgists lost running at 250 a year), is in a position to take its pick of the jobs offered. The subject's unpopularity is partly caused (according to Professor K. M. Entwistle) by "a reluctance to inject courses with an element which lets the students see that we recognise the responsibilities of science; that we see science as more than an intellectual exercise." Remedy: broader-based courses including economics, accounting and social science. This year's applications are up by more than 50% to something over 200. Image is also a problem in the chemical engineering department at UMIST, where it is feared that anything with the word 'chemistry' in it is equated with the word 'poison'. A broader course is seen as part of the solution again; this time it is subjects like pollution control, energy sources and foreign languages as a relief from the narrower mainstream of chemical engineering. A second brain drain is forecast when the Americans come to Britain to recruit for their energy-crisis programme, and since there is already a shortfall in chemical engineers produced, as against numbers required, they will become an even scarcer commodity than they are this year, when they can take their pick of jobs. Five years ago they were next to unemployable. Every other applicant for chemical engineering in the UK applies to UMIST, and what he gets for his money is an unsurpassed pilot plant to practice on, and a course with an entirely elective third year.

Signs of shifts in employment patterns

Colin Norman

After a period of rapid growth, enrolment in higher education in the United States is levelling off. The result is likely to be an increasingly bleak academic job market for scientists and engineers with PhD degrees and the trend has major implications for the nature of graduate education.

LAST month, a committee of eminent astronomers issued an unprecedented appeal for graduate education in astronomy to be cut back because of dismal employment prospects for new PhDs. Unless enrolment in graduate astronomy departments is substantially reduced, the committee said, the number of young scientists leaving universities in the United States with freshly minted PhDs in astronomy and closely related subjects could soon outstrip the number of available jobs by about six to one. Already, the committee noted, there are some 200 astronomers holding temporary postdoctoral appointments who have little chance of getting permanent jobs in astronomy.

Although extreme, the manpower situation in astronomy reflects problems which are being encountered in some other fields of science. In fact, if most projections are at all accurate, there is likely to be a growing imbalance between the supply of scientists and engineers with PhD degrees in a variety of disciplines and the number of jobs for which their training is directly suitable.

That prediction is based on two major trends affecting the manpower situation for PhD scientists and engineers. First, federal expenditures in most areas of science and technology have recently levelled off or even declined, and there is unlikely to be much real growth in support of basic research in the next few years. And, second, after a period of rapid expansion, higher education has entered a period of retrenchment. Overall enrolments in graduate and undergraduate departments have been declining and there is little chance that they will grow much over the next 20 years.

Although the reduced enrolment will tend to curb growth in the supply of scientists and engineers, it will also have a marked impact on the academic job market for PhDs—the declining growth rate in higher education will result in a similar reduction in new teaching positions in the universities, so that scientists and engineers emerging from graduate schools will increasingly have to look outside academia for employment. Superimposed on that trend, however, is the fact that prospective federal support for a few activities—such as energy research and development and possibly cancer research—is likely to create high levels of demand for scientists and engineers with both first and higher degrees in a few selected disciplines. In fact, according to some estimates, there may be severe shortages of people with some specific skills and that could distort the overall manpower picture drastically.

Those trends hold interesting implications for higher education and it should also be noted that they are both outside the direct control of the universities. The slowdown in overall growth is largely a consequence of the fact that the postwar 'baby boom' has now passed through higher education so that there is likely to be no growth in the college-age population for at least the next two or three decades. And the increasing support for energy research and development is coming directly from the federal government.

Boom and bust in the 1960s

In view of distortions created by previous federal programmes, college administrators are likely, however, to view with mixed feelings the prospective rapid increase in support for energy research. The situation which led to the call for cutbacks in enrolments in graduate astronomy courses is instructive in that regard. The call came from a special committee of the National Academy of Sciences, which met under the chairmanship of Leo Goldberg, Director of the Kitt Peak Observatory.

Like most other sciences, support for astronomy expanded rapidly during the early 1960s as part of the frantic post-Sputnik build-up of science and technology in the United States. But, just as young people began pouring out of the universities with PhDs in astronomy in the early 1970s, support for astronomy began to decline. The figures speak for themselves.

The number of PhDs employed in astronomy increased by 111% (from 623 to 1,313) between 1970 and 1973, and last year alone 180 astronomy PhDs were awarded. There are now about 900 students enrolled in graduate astronomy courses who will be looking for jobs in the next five or six years, and adding to the problem is the fact that astronomy has traditionally attracted PhDs from closely related branches of physics. Yet the committee estimates that there will be no more than 200 jobs available in the next five years.

At the root of the problem is the fact that funding for astronomy in general has been declining—federal support shrank from $227.3 million in 1968 to $186.8 million in 1972, the committee estimates. And there are scant prospects of any increase in the years ahead since the bulk of the funding now comes from NASA; with the shuttle taking up an ever-increasing share of the space budget, there is likely to be little money to spare for expanding space-borne astronomy, at least until the early 1980s.

Although it can be argued that astronomy is something of a special case, since job openings are largely confined to one sector—higher education itself—the situation there dramatically underscores one basic factor in supply and demand for highly trained manpower. The education process is so lengthy that periods of high demand and plentiful supply of trained individuals are often completely out of phase. Moreover, the trends which have led to the bleak manpower situation in astronomy—rapid expansion, followed by cutbacks, followed perhaps by constant or at best slowly increasing support—are evident in most scientific disciplines.

Overall, US expenditures on science and technology expanded rapidly during the early 1960s, but began to level off in about 1968. In fact, in terms of constant dollars, the total support for research and development declined between 1968 and 1971 before picking up slightly. The same pattern is evident in the total support for all higher education—the share of the gross national product devoted to it doubled between 1961 and 1972, from 1.1% to 2.2%, but has declined slightly since; and total enrolment in colleges and universities, after more than doubling during the 1960s, is levelling off.

In short, just as the universities were reaching peak output of graduates with first and advanced degrees in science, federal support began to shrink. The chief driving force behind those trends was the spectacular expansion of the space programme and its equally spectacular decline in the late 1960s. The result, of course, was that a huge oversupply of scientists and engineers began to emerge in 1970 and 1971 and much publicity was given to unemployment of highly skilled manpower.

According to surveys conducted by the National Science Foundation (NSF), in the spring of 1971 2.6% of all scientists and engineers with first or higher degrees were unemployed and looking for work, and in June and July of that year 3.0% of all similarly trained engineers were out of work. Younger scientists and engineers were the most severely affected (unemployment rates of 5.3 and 5.5% respectively) while PhDs only experienced unemployment rates of 1.4 and 1.9%. Although unemployment among scientists and engineers was running well below the national average (in excess of 6% at that time) the plight of unemployed scientific workers received widespread attention in the press and that may have contributed to declining enrolments in the early 1970s.

Two years ago, the National Science Board, the top policy-making body for the NSF, summed up the situation thus: "Substantial changes in the demand for scientists and engineers, which may be produced by factors such as a redirection in federal funding or the state of the national economy, may occur over periods of from two to three years. But because scientists and engineers require training extending over several years, serious imbalances of supply and demand, inadequacies of training, maldistributions among areas of competence, and similar problems may be corrected only over a longer five- to ten-year span."

A number of warning signs concerning the slow-down in the growth of higher education did, however, begin to turn up unexpectedly in the late 1960s, before the unemployment situation arose. According to data discussed at a meeting last year of science manpower analysts by Alan Cartter, of the University of California, Los Angeles, the following shifts took place.

The proportion of 17- and 18-year-olds graduating from high schools peaked in 1968 and has declined since; analysts had

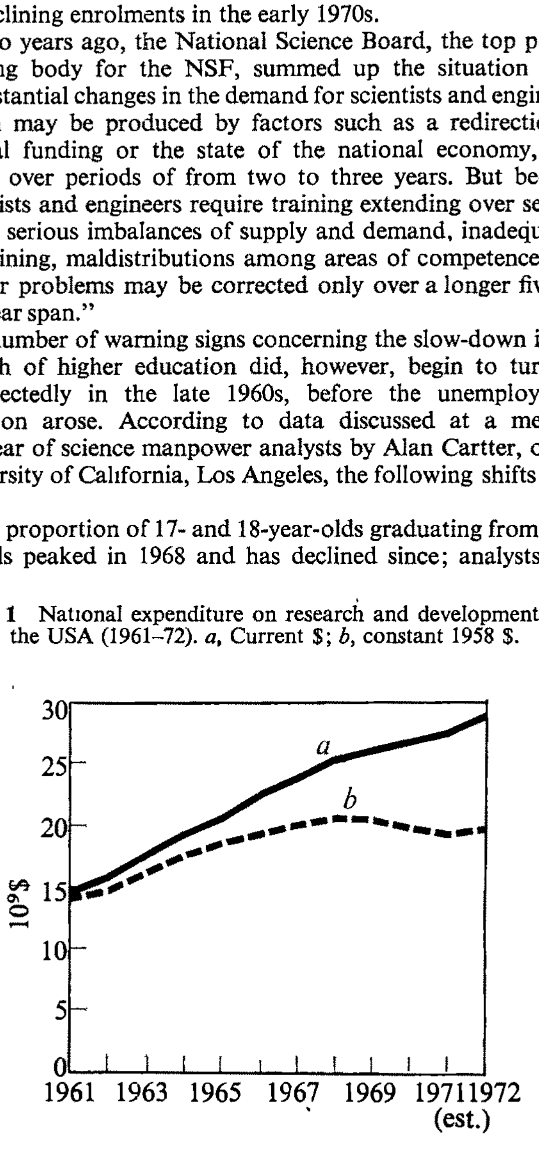

Fig. 1 National expenditure on research and development in the USA (1961–72). *a*, Current $; *b*, constant 1958 $.

Table 1 Summary of science/engineering doctorate labour force and use (1972 and 1985)

	Total	Physical sciences	Engineering	Mathematics	Life sciences	Social sciences
			1972 Estimate (thousands)

No. used as scientists or engineers as percentage of labour force	78	89	71	73	92	63

*Includes unemployed.

predicted a yearly increase of 1% until 1980. That was followed a year later by a sudden downturn in the proportion of high school graduates entering colleges and universities—again, the proportion had been expected to increase but between 1970 and 1973 it decreased from 61.8% of all high school graduates to 57.6%. That downturn was itself followed in 1970–71 by a peak in the college graduation rate. And, as for graduate education, enrolment in graduate courses peaked in 1967–68 and has generally been dropping ever since. Moreover, the PhD completion rate peaked in 1969–70.

Those trends have not been consistent among all the sciences. Enrolments in the life sciences and social sciences have generally held up, for example, and the number of women entering and completing graduate courses has continued to increase.

The latest survey of enrolment in graduate education, conducted by the NSF, indicates, for example, that enrolment in graduate engineering courses declined slightly last autumn and enrolment in physical sciences held about steady. But the number of students entering graduate social science departments rose by about 4.4% and enrolment in graduate biological science courses shot up by 17.2%.

Nevertheless, surveying future prospects, Cartter concluded that there is likely to be a slight contraction in total enrolment in higher education at least until the mid 1990s, which will depress the academic labour market. The oversupply of doctorates in the general academic labour market looks grimmer for the period 1980 to the early 1990s than it has at any time in the past.

That prediction is supported by at least three authoritative surveys. Last year, the Office of Education came up with projections of college enrolment in 1980 which suggest that the net increase in the number of full-time faculty members in the entire decade from 1972 to 1982 will be 34,000. That is fewer than were hired in the single year 1965 and compares with an addition of 211,000 full-time faculty members between 1962 and 1972.

More recently, the Carnegie Commission for the Advancement of Teaching predicted that enrolments in higher education are likely to grow slowly, if at all, during the next 10 years, after which they will probably decline. Slow growth may, however, be resumed after about 1995.

Finally, the NSF last month issued some grim predictions concerning the manpower situation for PhD scientists and engineers in the next 15 years. Those forecasts (*Projections of Science and Engineering Doctorate Supply and Utilisation 1980 and 1985*, NSF 75-301) indicate that there is likely to be a growing imbalance between the supply of PhD scientists and engineers and the number of job openings for which their skills will be required.

Specifically, the NSF anticipates the following developments:

- Based on an analysis of trends during the past five years, there are expected to be between 375,000 and 400,000 scientists and engineers with PhD degrees available to the economy by 1985. But there are likely to be only about 295,000 available positions in activities related to science and technology.
- That projection suggests "a trend toward increasing imbalances between supply and utilisation, which would result in more non-science and engineering utilisation of science and engineering doctorates, possibly in some unemployment".
- The NSF report notes, however, that the magnitude of unemployment is difficult to predict but it is likely to be relatively small since people with PhD training are likely to find some kind of employment, albeit outside science and technology or in occupations for which they are overqualified. In that regard, it should be noted that general levels of unemployment among scientists and engineers is now low, in spite of the fact that the United States is in the middle of a prolonged recession.
- There is likely to be a substantial shift in employment patterns, with increasing numbers of PhD scientists and engineers finding jobs outside higher education, or in jobs unrelated to science and technology. In fact, more than half of all new job openings for science and engineering PhDs are likely to be outside research and development in the next decade so that by 1985, more than a fifth of the entire doctorate science and engineering labour force will probably be employed in occupations unrelated to science and technology. Less than 10% of all PhD scientists and engineers are now so employed.

Those projections immediately raise a fundamental question about the nature of graduate education, namely, is the system which has traditionally produced people almost exclusively for academic and industrial research and development also suitable for producing PhDs for other occupations? Almost everybody who has studied the situation believes that a number of changes are required.

In addition to recommending cutbacks in enrolment, for example, the academy's astronomy committee also urged that PhD astronomy courses should be broadened so that the three-quarters of all would-be astronomers who will fail to get jobs in astronomy will be more employable elsewhere. Moreover, an *ad hoc* committee of the National Science Board recently recommended that "educational alternatives be provided to the traditional highly specialized PhD program to prepare students for a broad range of careers".

Those overall projections mask the fact, however, that there are likely to be shortages in a few fields because of rapidly increasing federal expenditures on a number of key programmes. Just as the space programme distorted the scientific manpower situation during the 1960s, the energy research and development programme and perhaps the cancer programme are likely to distort manpower demands in the next decade.

Although it is difficult to predict exactly how many trained people will be needed to carry out those two programmes, two recent studies have raised warning signals. As far as energy research and development is concerned, the National Planning

Association (NPA)—one of the better diviners of manpower trends—has concluded that "the future supply of engineers and scientists may be inadequate to meet the demands of activities designed to increase domestic energy supplies".

In short, the NPA reckons that the energy industry will need to recruit about 14,600 engineers and about 5,500 scientists a year by 1985. But, if recent enrolment trends in undergraduate engineering departments are maintained, the study suggests that only about 28,000 engineers will graduate from American universities in 1985. In other words, the energy industry will require more than half of all the engineering graduates, and about a third of all the graduates with degrees in the physical sciences. In 1970, by comparison, the energy industry employed only 10% of all engineers in the United States and 15% of all physical scientists. During the early 1960s, when there was high demand for scientists and engineers, many companies in the United States recruited from abroad; but the NPA study notes that supply of foreign engineers and scientists is diminishing.

There are, however, some indications that enrolment in engineering courses is beginning to pick up, perhaps in response to the possibility of a favourable job market. The Engineers Joint Council, for example, estimates that the freshman engineering class this year is 18% larger than last year's, and if that trend continues, the NPA's dire prediction that total output of engineering graduates will drop to 28,000 a year may turn out to be wide of the mark. The Engineers Joint Council also noted, however, that the declines in enrolment during the late 1960s and early 1970s resulted in a 5.5% drop in engineers graduating last year. Overall, 41,407 bachelors' degrees were awarded in engineering last year, 15,885 masters' degrees and 3,362 PhDs.

As for the cancer programme, the National Cancer Program Plan suggests that about 13,500 biomedical scientists with PhD or MD degrees will be required for cancer research in 1982. There were only about 5,500 scientists engaged in cancer research in 1972, and the plan suggests that "a deficiency in the number of scientists may begin to occur in [fiscal year] 1975 and may continue to increase as the program expands". It should be noted, however, that funding for cancer research is unlikely to grow as rapidly as the plan indicates and so manpower requirements will also grow rather more slowly. Moreover, enrolment in both undergraduate and graduate biology departments is continuing to increase. The NSF's projections for PhD scientists therefore indicate that there will be a close match between supply and demand for biological scientists in 1985.

In view of those predictions, it may well be asked what the federal government should do to bring supply and demand more closely into balance. First, it should be pointed out that the government's leverage on the supply side is surprisingly small. During the 1960s, for example, in spite of massive government support for science and technology, which included direct support of postgraduate students, the proportion of science and engineering graduates, as a percentage of the total numbers of graduates, remained constant (about 30% of all bachelors' degrees were awarded in science and engineering) whereas the proportion of PhD degrees in science and engineering even declined after 1962. Aside from direct support of postgraduates in energy-related fields, the federal government has recently phased out most of its direct support programmes for science and engineering students (much against the wishes of the universities, which have lost a useful source of income).

The demand side is likely to be influenced chiefly by enrolment patterns in higher education and by total government support for science and technology. As noted above, however, there is likely to be little growth in the college-age population and, therefore, in higher education. As for total government support of science and technology, if recent trends are anything to go by, a period of slow growth is likely to be in store for most areas of science, which at least will be an improvement on the stop-start trends of the late 1960s and early 1970s.

Indian scientific and technical personnel abroad

S. K. Roy

Manpower Division, Council of Scientific and Industrial Research, New Delhi, India

Although India educates large numbers of scientists and technologists, there is a considerable brain drain as a result of lack of opportunities for employment. To make full use of their trained manpower, the Indian government has started some schemes to help scientists who wish to return home.

MANPOWER being an essential input for any developmental programme, India adopted in the post-independence years a programme of rapid expansion of education in science and technology to meet the requirements for development of science and technology. The number of universities was gradually increased. Capacities for postgraduate education in the basic sciences were extended and the scope of technical education was broadened through the updating and expansion of the existing institutions and establishment of new ones A number of Regional Engineering Colleges and a chain of five Indian Institutes of Technology (IIT) came into being and the output grew rapidly each year. Table 1 illustrates the growth of universities and other institutions of higher learning and Table 2 the output, at different academic levels, of scientists, engineers and medical personnel. Although there were only 20 universities in India in 1947 the number had risen to 86 by 1972. Higher education and research in professional subjects such as agriculture and engineering attracted particular attention and some newly established universities were exclusively

for this purpose. The IITs were established as centres of excellence for education and research in engineering and technology. In the field of medical education, the number of colleges offering degree-level education rose from 15 in 1947 to 105 in 1974 and a few institutions were established exclusively for postgraduate education and research in medical sciences. A significant feature of this period is a proportionately large increase in the output of postgraduates in agriculture, engineering and medicine. The stock of scientific and technical personnel increased rapidly, as Table 3 shows. If the trends continue the estimated stock by the end of 1975 would be about 624,000 graduates in science, 229,000 postgraduates in science, 278,000 graduate engineers, 391,000 diploma engineers and about 117,000 medical doctors

But despite the expansion of facilities for higher education and research, a number of Indian scientific and technical personnel have continued to go abroad over the years. Education and training overseas is a century-old tradition with India's scientific and technical personnel; many qualified people go abroad for further studies, or training, or to acquire wider professional experience. Overseas exposure, especially in a developed country, helps expansion of one's academic, industrial, professional and social experience, and mature students can get particular benefit from it. The post-war period apparently opened up newer and greater opportunities abroad, and as a consequence the number of Indian scientists going abroad during the past 25 years has grown considerably. A good number are going for a first degree, with plans to work for subsequent higher degrees. Opportunities for employment in India have not developed along with the development of educational facilities and this has led a section of the educated unemployed to look for posts outside India. Most return home after a couple of years, some stay longer and others settle permanently in a foreign country. Over the past two and a half decades relatively larger numbers have been staying away for longer periods.

India's scientific and technical personnel abroad have been a matter of concern for some time and have generally found a prominent place in any discussion of the 'brain drain' from developing to developed countries. It is worth considering if all these scientists can be grouped under 'drained brains'. The Colombo Plan Consultative Committee, in its 22nd meeting in New Delhi in October and November, 1972 suggested "the external migration of personnel at the skilled, technical and professional levels for employment abroad under circumstances in which they could otherwise have been employed at once or in the near future, productively at their proper attained level of professional skill in their own country at work of national importance" as a definition of brain drain. From this definition, one might perhaps conclude that the number of Indians abroad constituting a brain drain is small. People planning to come home in the foreseeable future cannot be considered; it is those who have settled abroad more or less permanently and those who have not yet decided their time of return who constitute a potential brain drain.

Table 3 Stock of scientific and technical personnel

	Stock at the end of the year				
	1950	1955	1960	1965	1970
Scientists (graduates)	66,900	114,000	185,000	300,900	480,200
Scientists (postgraduates)	1,000	30,000	51,400	93,400	152,700
Engineers and technologists (graduates)	21,600	37,500	62,200	106,700	185,400
Engineers and technologists (diploma level)	31,500	46,800	75,000	138,900	244,400
Medical personnel (graduates)	18,500	29,000	41,600	60,600	97,800
Medical licentiates	33,000	35,000	34,000	31,000	27,000
Total	188,000	292,700	450,000	731,500	1,187,500

It is difficult to obtain a precise estimate of the amount of India's scientific and technical manpower that is abroad and even more so to collect details of their activities. A special section—the Indians Abroad Section—of the National Register of Scientific and Technical Personnel of India was started in 1958 to gather this information. Indian scientists, engineers, technologists and medical personnel abroad for study, further training or employment are encouraged to enrol in this section of the register. Although registration is voluntary, about 20,000 have enrolled so far (Table 4). About 50% of the registrants have since returned to India, which would leave about 10,000 still abroad. But this figure is believed to be far short of the actual number. On other available data it was estimated in early 1971 that 30,000 qualified Indians were abroad, of which 15,000 were engineers, 9,000 medical doctors and 6,000 scientists.

An analysis of the data in the Indians Abroad Register may be of some interest. About 90% of the 19,824 registrants are from four countries, the USA, the UK, Germany and Canada—the USA accounting for about 38% and the UK about 35%. Among those registered from the USA, scientists constitute the highest proportion (46%) followed by engineers (37%) and medical personnel (12%). Medical personnel and engineers form the highest proportion (39% each) among those registered from the UK, scientists make up 16%. Of the registrants from Germany, engineers are the largest group (63%) followed by scientists (22%); medical personnel constitute only 3%. Fifty per cent of the registrants from Canada are scientists and 33% engineers.

More than 50% of the scientists in the register enrolled from the USA, about 16% from the UK and about 10% from Canada. Among the engineers about 33% are from each of the USA and the UK and about 16% from Germany. About 70% of medical personnel are from the UK and a litle over 20% from the US.

Table 4 Progressive rise in the registration in the Indians Abroad Register

	Science	Engineering	Technology	Medicine	Social science	Management and/or accountancy	Total
1959	678	1,083	145	187	—	215	2,308
1960	975	1,685	280	295	—	270	3,505
1961	1,271	2,287	418	403	—	331	4,710
1962	1,586	2,735	510	583	—	375	5,789
1963	2,070	3,310	636	850	—	432	7,292
1964	2,495	3,945	707	1,175	—	471	8,793
1965	3,006	4,535	800	1,575	13	530	10,459
1966	3,413	5,000	892	1,910	76	552	11,843
1967	3,754	5,279	946	2,135	125	568	12,807
1968	4,048	5,513	988	2,384	154	574	13,661
1969	4,420	5,760	1,020	2,670	188	579	14,637
1970	4,790	6,015	1,050	2,945	239	594	15,633
1971	5,161	6,259	1,083	3,218	266	603	16,590
1972	5,497	6,567	1,107	3,385	305	606	17,467
1973	5,833	6,977	1,136	3,582	338	612	18,478
1974	6,131	7,274	1,171	3,726	351	617	19,270
1975	6,330	7,455	1,188	3,855	374	622	19,824

Table 4 also reveals that the number of Indian scientists enrolling in the Indians Abroad Register is progressively diminishing. Whether this is because of a gradual decrease in opportunities abroad in recent years can only be guessed.

The other interesting fact is that almost all the registrants state their intention of returning to India sooner or later. This obviously brings out the weak side of the register. People who have more or less settled abroad or persons who are undecided about their return do not bother to enrol. Most registrants are on academic assignments but the numbers employed in industry, particularly in production, and those holding senior positions in academic fields are low. A special effort to collect information about such personnel has been initiated recently by the Indian Missions in some developed countries.

India's scientific and technical personnel abroad, properly harnessed, can contribute a great deal. It is, therefore, a question of what can be done to facilitate their return and to use them effectively once they have come back. The usual procedure of recruitment in India, especially to jobs in the public sector, acts as constraint on quick absorption in regular employment. It was, therefore, necessary to evolve a scheme which would ensure temporary placement, at least for those better qualified, on their return from abroad. The Indian government, therefore, instituted in 1959 the 'Scientists Pool' for the temporary employment of well qualified Indian scientists, engineers, technologists and medical personnel, particularly those returning from abroad without a job. Later, social scientists were also brought within the purview of the pool scheme. Persons with high qualifications, who have not been abroad are also considered for the pool—an unorthodox system of temporarily employing and making use of highly qualified people while they look for regular employment through the usual channels. Selections for the pool take place on a continuous basis throughout the year. Everybody enrolled in the Indians Abroad Register is automatically considered for selection near the time of their return, provided they do not have a job in India. The Scientists Pool is operated by the Council of Scientific and Industrial Research at New Delhi.

Those selected are attached to appropriate organisations and receive a salary (actually more of a stipend) from the Council of Scientific and Industrial Research. Any scientist in the pool is free to try for any job in India and leaves the pool on securing one Pool appointments are for a period of one or two years. If a pool scientist is not able to find a regular job within this period, his case is reviewed and the appointment may be extended.

Table 5 gives a breakdown of the number of people in the pool. Up to the end of February 1975, some 10,753 persons had been selected, of whom 9,889 were from the Indians Abroad Register. Of these, 6,163 returned to India and 3,635 of them secured regular employment in India after working for some time as a pool scientist; another 1,070 were able to find a regular job without help from the pool. About 900 other people are believed to have settled in India in regular employment as they did not respond to pool enquiries.

The pool scheme does, however, have its inherent limitations. As pool scientists are only temporary, the user organisations are unable to give them long term assignments. Nevertheless, many pool scientists produce good work and many organisations are keen to obtain scientists, engineers and doctors through the pool system.

An opinion survey of ex-pool scientists, carried out by the CSIR in 1969–70, found that most of them were fully satisfied and nearly all were happy with at least some part of the scheme. There was some dissatisfaction arising from temperamental differences, high expectation, and conflict of interest between the internal staff and the pool scientist. Nevertheless, 46% of the respondents stated that the pool placement gave them confidence to return, 53% felt that it gave a ready working opportunity and 67% appreciated the financial benefit so necessary at the beginning. The pool scheme can, therefore, be considered to have been of considerable help to Indian scientific and technical personnel returning from abroad.

The Indian government also approved a scheme of supernumerary appointments for the quick absorption of outstanding scientists whose services might be useful for research and development projects. The posts are to be specially created for them and salaries appropriate to their background can be offered. The scheme has, however, been used only cautiously so far.

Table 5 Scientists pool

	Science	Engineering	Technology	Medicine	Social science	Total
1959	77	69	26	25	—	197
1960	50	60	15	38	—	163
1961	240	160	26	98	3	527
1962	120	79	28	159	7	393
1963	185	365	37	247	5	839
1964	265	485	37	345	7	1,139
1965	324	321	49	266	8	968
1966	205	162	33	219	10	629
1967	187	156	24	220	20	607
1968	263	113	20	191	12	599
1969	321	167	18	219	18	743
1970	280	151	15	227	9	682
1971	364	215	18	160	14	771
1972	356	369	21	164	27	937
1973	249	245	16	138	10	658
1974	363	253	24	178	19	837
Total	3,849	3,370	407	2,894	169	10,689

Although the schemes of the scientists' pool and supernumerary appointment help those who return to India, they have not proved sufficiently attractive to those undecided about their return or those who have settled abroad. Even though it is not possible to bring back every Indian abroad, some attempt to make use of their talent for specific purposes is worthwhile. Some may visit India for a short time in a professional capacity. Their association with research and development organisations or academic institutions in India may be of mutual interest. Schemes of short term appointment as research associates or visiting scientists have recently been introduced by the Council of Scientific and Industrial Research. People visiting India for a short time can be offered such appointments in national laboratories in cases where their background fits the requirements of the organisations. In the academic field, the universities in India are now in a position to offer short term appointments to Indian scholars abroad during their sabbatical leave. Apart from the immediate gain, such associations provide people with the opportunity to become acquainted with conditions in India and may induce them to stay permanently The Indian government has also recently approved a 'package scheme' to enable Indian scientists and technologists engaged in production or management in industrial organisations abroad to set up manufacturing units in India. They will be helped to secure industrial licences, capital goods clearance and import licences, and if necessary entrepreneurial loans from public financing bodies in India, and to obtain infrastructure facilities such as land, water and power supplies. The Council of Scientific and Industrial Research is the executive agency of the scheme, but its recent introduction means that its impact is yet to be felt
